JOURNAL OF
CONSULTING
AND
CLINICAL
PSYCHOLOGY

AMERICAN PSYCHOLOGICAL ASSOCIATION

ISSN 0022-006X

The *Journal of Consulting and Clinical Psychology* publishes original contributions on the following topics: (a) development, validity, and use of techniques of diagnosis and treatment in disordered behavior; (b) studies of populations of clinical interest, such as hospital, prison, rehabilitation, geriatric, and similar samples; (c) cross-cultural and demographic studies of interest for the behavior disorders; (d) studies of personality and of its assessment and development where these have a clear bearing on problems of consulting and clinical psychology; (e) case studies pertinent to the preceding topics. In order to improve the use of journal resources it has been agreed by the two Editors concerned that the *Journal of Consulting and Clinical Psychology* will no longer consider manuscripts dealing with the etiology or descriptive pathology of abnormal behavior, and the *Journal of Abnormal Psychology* will no longer consider articles dealing with the diagnosis or treatment of abnormal behavior. Articles that appear to have a significant contribution to both of these broad areas may be sent to either journal for editorial decision. Papers of a theoretical nature will also be considered within the space limitations of the journal.

Manuscripts: Submit manuscripts in triplicate to the Editor-elect, Sol L. Garfield, Department of Psychology, Washington University, St. Louis, Missouri 63130 according to instructions provided elsewhere in the journal. Authors submitting a manuscript previously considered for publication in another APA journal are invited to inform the Editor, who will then seek to obtain independent reviews, thus avoiding the possibility of repeated reviewing by the same consultant.

Copyright and Permissions: All rights reserved. Written permission must be obtained from the American Psychological Association for copying or reprinting text of more than 500 words, tables, or figures. Permissions are normally granted contingent upon the permission of the author, inclusion of the APA copyright notice on the first page of reproduced material, and payment of a fee of \$10 per page, table, or figure of APA material. Permission fees are waived for authors who wish to reproduce their own articles. Address requests for permission to the Permissions Office, American Psychological Association, 1200 Seventeenth Street, N.W., Washington, D.C. 20036.

Subscriptions: Subscriptions are available on a calendar year basis only (January through December). Nonmember rates for 1971: \$32 domestic, \$34 foreign, \$6 single issue. APA member rate: \$16. Write to Subscription Section, APA.

Reprints: Authors may order reprints of their articles from the printer when they receive proofs.

Back Issues and Back Volumes: For information regarding back issues or back volumes write to Order Department, APA.

Microform Editions: For information regarding microform editions write to any of the following: Johnson Associates, Inc., P.O. Box 1017, Greenwich, Connecticut 06830; University Microfilms, Ann Arbor, Michigan 48106; or Princeton Microfilms, Princeton, New Jersey 08540.

Change of Address: Send change of address notice and a recent mailing label to the attention of the Subscription Section, APA, 30 days prior to the actual change of address. APA will not replace undelivered copies resulting from address changes; journals will be forwarded only if subscribers notify the local post office in writing that they will guarantee second-class forwarding postage.

Published bimonthly (beginning in February) in one volume per year by the American Psychological Association, Inc., 1200 Seventeenth Street, N.W., Washington, D.C. 20036. Printed in the U.S.A. Second-class postage paid at Washington, D.C., and at additional mailing offices.

On the Long-Range Effects of Concentration Camp Internment on Nazi Victims: 25 Years Later

Netta Kohn Dor-Shav
Bar-Ilan University, Ramat-Gan, Israel

This study investigated long-range effects of concentration camp internment on survivors. The underlying hypothesis was that the extreme and prolonged stress suffered by victims could be expected to have resulted in impoverishment of personality and dedifferentiation in both personality and perceptual-cognitive functioning. Subjects were 42 survivors, 26 males and 16 females, ranging in age from 42 to 67, and 20 controls, 9 men and 11 women, of similar age, background, and education but who had escaped incarceration. The study was carried out in Israel, using a double-blind paradigm. All subjects were tested with three of Witkin's measures of psychological differentiation, the Embedded-Figures Test, Human-Figure Drawings, and the Block Design subtest of the Wechsler Adult Intelligence Scale. They were also given the Rorschach Inkblot Test, the Bender Gestalt Test, and the 16 Personality Factor Questionnaire. Findings tend to support the hypothesis. Survivors manifested evidence of impoverishment and constriction of personality and appeared to be less accessible, less connected, and more labile. In perceptual-cognitive functioning, they tended to be more global, less complex, and less differentiated, and there were indications of breakdown of ego boundaries. Some evidence suggests that earlier incarceration led to more severe impairment. The price is still being paid!

Although it is more than a quarter of a century since the liberation of Aushwitz in January of 1945, it is still difficult to address oneself objectively to the effects of that holocaust on those few who survived. Nevertheless, it was felt that if the survivors of that ineffable madness were not reached soon, scientific assessment of the sequelae of concentration camp internment would be made impossible by the passage of time.

The present study, therefore, was initiated 25 years after the liberation in an attempt to ascertain the price paid—and still being paid—by the victims of the most inhuman stress experience ever perpetrated by man against man before it became too late to reach the victims.

This study was carried out with the help of funding granted by the Committee for Research of Bar-Ilan University. The author gratefully acknowledges the support given.

Requests for reprints should be sent to Netta Kohn Dor-Shav, Department of Psychology, Bar-Ilan University, Ramat-Gan, Israel.

The psychological literature, of course, reflects considerable interest in the effects of laboratory-induced or situational stress, as well as in the aftereffects of stress experiences such as that of the prisoner-of-war, criminal imprisonment, sensory-deprivation states, and natural and man-made disasters.

However, none of these compare with—and only the prisoner-of-war experience in some cases approached—the degree of stress experienced in the concentration camp, a stress situation that taxed to the extreme human ability to survive in the face of manifold, prolonged, and unprecedented stresses.

It was, of course, recognized immediately after the liberation that the camp experiences had left indelible effects on the few pathetic survivors (Boder, 1949; Grygier, 1954; Nierembski, 1946). Unfortunately, though understandably, however, no scientific, systematic study of survivors has been undertaken over the years. There have been, in fact, only a very few studies, and these tended to focus on attitudes, adjustment, clinical

symptomatology, and life-style—suggesting a unique, long-lasting syndrome among survivors characterized by chronicity, vagueness, depression, fatigue, sleep disorders, emotional lability, blunted affect, and withdrawal (Chodoff, 1963; de Wind, 1968; Niederland, 1968; Simenauer, 1968). Also noted were the absence of psychotic symptomatology and difficulties in interpersonal relationships.

Thus a review of the literature found no studies that attempted to assess the intellectual and perceptual-cognitive functioning of the survivors, nor were there studies aimed at a comprehensive and objective evaluation of personality functioning; no attempts to identify, assess, and define the nature of the psychological deficit or to examine the personality structure and function of survivors in a controlled study seemed to have been made. It was to fill this gap that the present study was undertaken.

Specifically, the study made use of clinical psychological tests and research measures in an attempt to assess the personality functioning, ego boundaries, and perceptual-cognitive processes of concentration camp victims.

Underlying hypotheses were that the severe and prolonged stress endured by survivors may be expected to have resulted in impoverishment of personality, a process of dedifferentiation in the perceptual-cognitive sphere, and primitivization in both personality and perceptual-cognitive functioning.

Thus the research aimed to answer the following basic questions: (a) Is there evidence of primitivization and/or dedifferentiation in perceptual cognitive or personality functioning of survivors? and (b) Are there demonstrable decrements or differences in personality structure or functioning in a group of survivors as compared to controls? In addition, the study was interested in ascertaining if there was evidence of breakdown of ego boundaries, differential effects related to age at the time of incarceration, or actual brain damage.

Method

Subjects

There were a total of 62 subjects of both sexes in the study, ranging in age from 42 to 67, and living

within the greater Tel Aviv area in Israel. All subjects were tested individually in their homes or places of work. Testing sessions lasted from 2 to 3 hours.

Group 1, the main experimental group, consisted of 42 survivors (26 men and 16 women), who had been incarcerated in the most severe of the Nazi concentration camps during World War II. Subjects in this group were taken from a list supplied by Yad Vashem, the Israeli organization instituted devoted to the memory and study of the holocaust with whom all survivors in Israel are registered. Of those included in the study, 13 had been interned at Auschwitz, 5 at Bergen Belsen, 6 in Maidanek, 1 in Treblinka, and 10 in other camps. Ages in this group ranged from 42 to 67.

Group 2, the control group, consisted of 20 subjects (9 men and 11 women) matched to subject in Group 1 for age, academic training, occupation and place of origin. These subjects were chosen via the population registry and were contacted individually. (As there were, unfortunately, an unexpected number of refusals, the *N* for this group is considerably smaller than that for Group 1. The subjects in this group ranged in age from 42 to 65.)

Measures

Each subject was tested with a battery of tests chosen for their appropriateness for measuring perceptual-cognitive and personality functioning.

Three measures of psychological differentiation as defined by Witkin, Dyk, Faterson, Goodenough, and Karp (1962) were included.

1. The Embedded Figures Test (EFT). This test, introduced by Witkin et al. (1962), is considered to be a basic and reliable measure of psychological differentiation. The subject is required to disembed, from within a complex geometrical constellation, a previously presented simpler figure that has been integrated into the new context.

2. The Human Figure Drawing (HFD), as a measure of psychological differentiation, is scored for degree of sophistication and articulation of the body concept.

3. The Block Design subtest of the Wechsler Adult Intelligence Scale (WAIS) is one of the performance subtests considered by Witkin et al. to be a measure of psychological differentiation. It was chosen for the present study because it is also a measure of abstract functioning and is therefore relevant for the assessment of a hypothesis of brain damage.

In addition, the battery included (a) the Rorschach Inkblot Test, a measure of both perceptual-cognitive as well as of personality functioning; (b) the Bender Gestalt Test, a test of psychomotor as well as of perceptual functioning, included primarily to assess the tenability of a hypothesis of brain damage; and (c) the Sixteen Personality Factor Questionnaire (16 PF): This questionnaire, developed by Cattell (1967), yields 16 factors reflecting independent dimensions of personality functioning. It was chosen because it is one of the few reliable per-

validity questionnaires that has been carefully translated into Hebrew and for which norms are in the process of being established in Israel.

Design and Procedure

To mitigate the effects of possible bias, the study was conducted using a double-blind paradigm. Only one assistant (the one in charge of identifying, locating, and contacting subjects, as well as of providing testers with lists of individuals to be tested and of keeping records) knew to which group a particular subject belonged.

Data were gathered by a total of five testers, working two or three at a time. Each tester was carefully trained and supervised by the chief researcher before being allowed to test subjects in the field. Testers did not know the purpose of the study or the nature of the sample groups, nor did they themselves score the tests in the battery. Testers were given lists of subjects to be tested, and they contacted the subjects and tested them individually at the subject's home or place of business. Testing sessions lasted 2-3 hours. Testers were MA students in psychology, with one exception who was in the last year of BA studies.

Scoring was done by a total of three scorers, all of whom were MA candidates in psychology. Again, in accord with the double-blind nature of the study, the scorers remained ignorant of the purpose of the research, as well as of the nature of the sample groups included.

Interrater reliability for scores used was ascertained and was uniformly high, ranging from .42 to .99. (See next section.) However, in the interest of facilitating data processing, one of the scorers whose own intrarater reliability was excellent ($r = .89$) rescored all protocols. It was these scores that were used in the final statistical analyses.

Scoring

Tests in the battery were scored according to the following criteria: (a) for the EFT, the score used was the total time in seconds that the subject took to disembed the 12 figures, with a maximum of 180 seconds assigned for any one figure or for failure (Witkin et al., 1962). (b) The Block Design subtest of the WAIS was assigned its scaled score value. (c) HFDs were scored according to the 9-point version of the Marlen scale (Dershowitz, 1971; Witkin et al., 1962). (d) Rorschach protocols were scored both according to standard clinical methodology as well as for cognitive-differentiation complexity using specially developed criteria described below. (A detailed account of the scoring method and criteria is under preparation for separate publication.)

Briefly, a number of scores, as well as a differentiation index and complexity ratio, were developed to reflect the degree of differentiation, integration, and complexity of the Rorschach responses given by the subject.

Thus *WA* and *WD* are both scores reflecting undifferentiated whole responses, with the former referring to simple, vague, or global gestalts and the latter to simple aggregates of unintegrated or undefined forms (e.g., "bunches of cotton" on Card 7).

WB and *WC*, conversely, are scores reflecting both differentiated and relatively complex percepts, as well as ones having a good deal of integration; the distinction between the two is that *WB* is assigned to responses that seem to progress from the whole to the parts and *WC* for the reverse process. (*WB* responses are relatively rare in any population.)

In addition, two composite scores were developed. The first of these, the differentiation index, reflects not only the quality of the whole responses but also the number of parts or details of the blots that were specifically included in the percepts, as well as the total response pattern. Thus the higher the index, the better the level of articulation and integration.

Specifically, the formula for the differentiation index used is:

$$\frac{[3 (WA)] + [3 (WB) + ND_L] + [3 (WC) + ND_S] + [3 (WD)] + ND + \frac{1}{2} Nd}{R}$$

where *WA*, *WB*, *WC*, and *WD* reflect the qualities described above, *ND_L* and *ND_S* refer to the large details of these differentiated responses, respectively, and *ND* and *Nd* refer to the total number of large detail (*D*) and small detail (*d*) responses given independent of the whole responses. The denominator, *R*, refers to the total number of responses in the protocol.

The complexity ratio reflects the degree of complexity and differentiation of the Rorschach whole responses by contrasting the number of simple, global amorphous responses to the differentiated, complex ones. Thus the formula for the ratio is

$$\frac{WB + WC}{WA + WD}$$

The higher the ratio, the more complex and articulated the responses.

With regard to the reliability and validity of these specially developed measures, the following was found:

Interrater and intrarater reliabilities for *WA* and *WB* were better than .90 ($p < .02$), and for *WB* and *WC* reliabilities ranged from .56 to .78 ($p < .05$). For the differentiation index reliabilities were better than .88 ($p < .02$). (Reliabilities for the complexity ratio, as it is simply a mathematical function of *WA*, *WB*, *WC*, and *WD*, were not computed separately.)

In addition, in conjunction with an earlier study that may be considered a pretest with respect to the present one, test-retest data yielded reliability coefficients for the scores and indices significant at between .05 and .001.

With regard to validity, of course, the problem is more complex. A cogent argument for face and content validity can be made based on the nature of

the procedures and criteria used. The fact that the measures differentiated between groups, according to prediction, in a number of pretests using independent variables such as age and current stress—as well as in the present study (see Results)—is also considered to be in a sense validating.

The 16 PF was scored for its component factors, and these scores were compared across groups.

Results

Addressing ourselves first to the data relevant to the hypothesis that the severe and extreme stress endured by the concentration camp victims would manifest itself in decreased differentiation, survivors were compared to the control group on those measures that were considered relevant for cognitive-complexity differentiation, that is, the EFT, the Block Design subtest of the WAIS, the HFD, and the especially developed Rorschach measures described in the preceding section. Table 1 summarizes these findings and also includes data for the Bender Gestalt test.

Inspection of the data in Table 1 shows that no differences were found between group means on the EFT, BD, or HFD, nor were there significant differences on the Bender.

With regard to the Rorschach, findings were mixed, with support for the hypothesis emerging only from significant differences on the differentiated *WC* measure, as well as for the complexity ratio, though there was also evidence of trends in the expected direction for the *WA* and *WB* scores, as well as for the differentiation index.

It had been noted, however, as inspection of Table 1 shows, that there was a great deal of variability with regard to the EFT, Witkin et al.'s (1962) basic measure of psychological differentiation, especially among the concentration camp group. Upon analysis, this difference yielded an *F* of 2.28, significant at the .05 level—a finding that in itself indicates, at the very least, that the two groups cannot be considered as having come from the same population. Similarly, a significant difference in variability between the groups was found for the differentiation index ($.05 < p < .10$).

This was confirmed in a nonparametric analysis, in which the groups were each divided into *high*, *medium*, and *low* performers.

* Asterisks indicate significance.

The difference between the groups was found to be significant at the .10 level of confidence (one-tailed).¹

With regard to the HFDs that had not

¹ It should be noted that due to the considerable difficulty, in general, in obtaining significant differences in clinical research, it was decided to accept the 10% level of confidence.

in this analysis, shown any significant differences between groups when scored according to the Marlens scale, it became apparent during subsequent content analyses (not reported here) that the drawings of the concentration camp group tended to be rendered with fragmented broken lines, with vague gestalt, and with inconsistency in the level of detail. Thus, such drawings might include secondary features or items of dress, and even accessories, while omitting essentials. Such differences, however, did not necessarily reflect themselves in the scoring, as a drawing with fragmented lines, which indicated sex and included most body parts, although having obvious evidence of a breakdown of the body boundary concept might well get a better score, than a relatively "healthy" stick figure or a "snowman." These stick figure and snowman styles, however, though obviously undifferentiated and rather primitive, do not reflect a breakdown of ego boundaries. It was decided, therefore, to submit the drawings to a senior clinical psychologist with instructions to separate them into two groups, those that he thought belonged to concentration camp victims and those not. The prediction was clearly significant, $\chi^2(1) = 9.47$, $p < .01$, indicating that on a global comparison, clinical differences are apparent and that the drawings can be differentiated.

At this point—especially due to the variability of the scores—it was decided to ascertain whether age was a factor that should be taken into further account. With an age range of from 42 to 67, it was reasonable to assume that there were a considerable number of subjects included for whom a diminution of powers might be expected on the basis of age alone.

Accordingly, both concentration camp and control subjects were divided into above 50 and 50 and below brackets, and comparisons were made for the scores. This analysis confirmed that age was indeed a factor on the differentiation index, as well as for the Bender.

This led to a replication of all analyses for the perceptual-cognitive and differentiation measures, excluding subjects above 50 in both groups. Table 2 presents the findings.

As will be noted from Table 2, excluding

the older subjects, as expected, sharpened the findings, resulting in considerable support of the hypothesis. For Witkin et al.'s measures of psychological differentiation it was found that although findings for the EFT were not significant, the Marlens ratings for the HFD yielded significant differences for both the male and female drawings in the predicted direction.

With regard to the special Rorschach scores, the differentiation index yielded a significant difference between the groups, the level of significance for the WC measure was

increased from .08 to .02. (No computation was made for the complexity ratio for the younger subjects taken alone, since it was apparent that any differences obtained would reflect the difference on *WC* with some contribution from the trend ($p < .20$) for an increase in *WA* in the concentration camp group.)

For the Bender, too, the elimination of the older subjects resulted in a significant difference between the groups, $t(24) = 1.60$, $.05 < p < .10$, one-tailed.

Of considerable interest, of course, was the

analysis of the Rorschach in accordance with the usual scoring methods. Thus the Rorschach protocols were rated not only for cognitive-differentiation complexity but also for the generally accepted formal and content criteria. Tables 3 and 4 present the results for Rorschach determinants and content, respectively, for the concentration camp and control groups as a whole. Table 3, in addition, presents data for the Combined Color (Sum C) and Fisher Penetration scores.

As will be seen from the table, there were significant differences between the groups in the predicted direction for the Human Movement ($.05 < p < .10$), Texture ($p < .05$), and Pure Color ($.05 < p < .10$) determinants, respectively. In addition, there was a significant difference ($.05 < p < .10$) on the Form

Primary measure, favoring the concentration camp subjects. (Preliminary indications with regard to Productivity and the Form + %, reflecting deficits in the concentration camp group, were not confirmed, although slight trends remained in the predicted directions.) The differences for the Sum C— and the Fisher Penetration scores were not significant.

With respect to content, as will be noted, concentration camp victims, as expected, gave significantly fewer *abstract* responses ($p < .01$), *nature* responses ($p < .01$), and sex responses ($.05 < p < .10$). In addition, again as would be expected, they tended to give more animal responses ($.10 < p < .20$) and showed a weak trend toward an increase in incidence of *fire* responses.

Next, because age was a serious factor in our analyses for the cognitive-differentiation complexity Rorschach measures, it was decided to also compare several of the traditional Rorschach measures for the younger subjects only. Table 5 summarizes the findings.

As can be noted from Table 5, this analysis again yielded a significant difference for the Pure Color determinant, as well as a significant difference on Color Primary. Findings for the Texture and the Form Primary determinants, however, were weaker than for the entire sample, though strong trends remained ($ps < .10$ and $.13$, respectively).

Finally, scores on the 16 PF were compared for each scale, both for the whole samples as well as for the younger subjects taken separately. Tables 6 and 7 present these data, respectively.

As can be noted from the tables, only the Imaginative scale showed a significant difference between the concentration camp and control groups, with trends apparent also for the Conscientious and Experimenting factors. Taking the younger subjects alone, only the Shrewd and Controlled scales yielded significant differences, with a trend evident for the Self-sufficient factor also. Adopting the standard meanings of the factors for the purpose of interpretation—as well as adopting a considerable degree of caution—we find that as expected, concentration camp victims were rated as more practical, careful, and conventional than the controls (Imaginative). They

tend to be more conservative, staid, and persevering (Conscientious), as well as being more likely to accept established ideas and more tolerant of traditional difficulties (Experimenting). For the younger subjects only, the differences indicated the victims to be more penetrating, more shrewd, more calculating, and more worldly (Shrewd); less disciplined and more likely to follow their own urges and to disregard protocol (Controlled); as well as tending to be more group dependent and more prone to group adherence than the controls (Self-sufficient).

It should be noted that although no predictions had been made with regard to the subscales of the 16 PF before the project was initiated, they were made before the data were analyzed. All findings, with the exception of those for the Controlled scale were

predicted, though a number of scales for which predictions had been made did not show significant differences.

Discussion

Findings are discussed first in terms of the hypothesis predicting a deficit in cognitive-differentiation complexity for the concentration camp victims, after which the question of personality functioning and possible impoverishment will be addressed.

It was expected that the severe and prolonged stress undergone by the survivors could be expected to have resulted in a process of dedifferentiation and primitivization in the perceptual-cognitive sphere, as well as in personality structure and function. Obviously, it is not possible to demonstrate dedifferentiation or change retroactively; however, data in support of a hypothesis of differences between the groups on the measures allow us to draw inferences with regard to the hypotheses.

On measures of psychological differentiation taken from Witkin et al. (1962), findings were mixed. For the EFT a significant difference was found in variability between the groups, and chi-square was significant at the .10 level, lending some albeit inconclusive support to the hypothesis. The Block Design subtest of the WAIS did not differentiate, and the HFD, rated according to Marlen's scale, did not differentiate between the groups when the entire age range was included. However, when the older subjects were excluded from the analysis, ratings for psychological differentiation of the drawings yielded significant differences between the groups for both the male and female drawings as predicted.

The above findings, in themselves, indicate some support of the underlying hypothesis.

The failure to find differences on Block Design may be explained by what is, in effect, below-par performance within a rather narrow range for both the concentration camp and the control groups. This finding may be a function of the tendency, found in other studies (Dershowitz, 1971), for Jewish subjects at various age levels to do relatively poorly on the performance subtests of the

WAIS, as well as on other measures of psychological differentiation. Thus the fact that group differences were found for the EFT and HFD lends more support to the hypothesis of dedifferentiation here.

It is from the special, original Rorschach measures of cognitive-differentiation complexity that considerable additional support was obtained for the hypothesis, however. Thus, when the groups as a whole were compared to each other, differences were found on the WC measure, indicating a lower incidence of well-articulated and integrated whole responses among the survivors and an overall lower complexity ratio, which reflected the relative frequency of simple, amorphous, non-articulated responses as compared to differentiated, well-articulated, and integrated ones. Further, when the older subjects were excluded from the analysis, we found that the difference on the differentiation index, which had only shown a trend for the groups as a whole, became significant. This measure, because it takes both the qualitative and the quantitative aspects of Rorschach responding into account, is considered to be the most sensitive of the measures for cognitive-differentiation complexity. Thus the finding of a difference at better than the .10 level in the predicted direction lends considerable support to the hypothesis.

Some difficulty is encountered in addressing the question of whether the eventual amount of impairment was greater for victims incarcerated at an earlier age, as has been suggested in the literature regarding survivors (Eitinger, 1964). Obviously, it is the older group of victims who were interned at a later age; however, comparison of older to younger subjects cannot ignore the effects of the aging process itself, which seems to mitigate the differences between the concentration camp and control groups when taken as a whole. The fact that significant differences with age were found within the control group for several of the perceptual-cognitive measures, that is, the EFT, the Bender, the WC, and the HFD, indicates that the involutinal process per se leads to poorer performance of these measures. It becomes all the more interesting, therefore, to note that for the con-

* Asterisks indicate significance.

centration camp victims, but not for the controls, there was evidence of a *reversal* on the differentiation index, with younger subjects having significantly lower indices, $t(41) = 2.24$, $p < .02$. As other research has shown a *decrease* with age for this index, the present finding, in effect, lends some support to the hypothesis that incarceration at an earlier age was more damaging.

At this point, the data for the Bender become of considerable interest as well. It can be recalled that when all subjects were taken together, there was no significant difference between the groups. However, when the older subjects were excluded from the samples, a difference between the concentration camp and control groups did obtain. This finding—especially in view of the fact that here, as in the case of the differentiation index, a significant intragroup difference between older and younger subjects was found in the control group but not in the concentration camp sample—can be interpreted as reflecting greater deficit in the younger subjects. Regarding the possibility of actual brain damage among concentration camp victims, the findings remain inconclusive. Though the Bender might suggest damage in the younger subjects, there is no reason to suspect that head trauma as such would be directed more at younger subjects than at older ones. Furthermore the Block Design scores, which are also sensitive to brain damage when it is present, were, if anything, better for the concentration camp group both when the samples were taken as a whole, as well as when only the younger subjects were included, though the difference was of course not significant.

Looking at personality functioning, it was found, as predicted, that there were significant differences between the groups on a number of standard Rorschach scores—in particular on those that measure full, rich, open, and creative functioning. Thus the Rorschach measure that reflects the quality of the inner life, creativity, and perception of the other (the Human Movement response) indicated that concentration camp survivors gave fewer such responses, reflecting a more constricted, impoverished inner life, decreased creativity, and limitation in the perception of the human

"other." The lower incidence of the Texture determinant shows, as predicted, that the survivors had greater difficulty in being accessible to others and in being connected, aware, and open, whereas the increase in Color Form and Color Primary indicate poorer emotional control. In addition, the data indicating significantly fewer *abstract*, *nature*, and *sex* responses also indicate a more restricted, impoverished inner life, whereas the trend to an increase in the number of Animal responses suggests the possibility that for these subjects, the animal has, in a sense, come to replace the human. This interpretation, though of course highly speculative, is given some support by the fact that the animal responses in these protocols are very frequently given in generic, rather than in specific, terms, something that is relatively rare otherwise. Thus we do not find names of specific animals, but rather, "an animal," "a wild animal," "a beast of some sort," "behemoth," and so on, responses that it is felt reflect the subject's experiences with the wild beast unleashed in man and the absence of man's humanity.

From the 16 PF, we found that the survivors, on the whole, tend to be more conservative, careful, conventional, and practical, as well as more staid and persevering—qualities that are consonant with the picture of greater constriction and lessened differentiation gleaned from the Rorschach data. In addition, the suggestion that the survivors tend more to follow their own urges and to be disregarding of accepted protocol fits the finding of an increase in Color Form and Color Primary on the Rorschach. The finding (Self-sufficient) that the survivors tend to be more group dependent and more prone to group adherence supports suggestions to that effect in the literature (Bondy, 1943) and would seem to indicate a basic seeking for safety and affiliation within a group, rather than genuine interaction and belonging.

Taken as a body, then, the data can be seen as providing evidence pointing to impoverishment and dedifferentiation, among concentration camp survivors, in both perceptual-cognitive and personality functioning. The clinical picture is made even more poig-

nant when we consider that the survivors, though tending to seek affiliation and group belongingness overtly, are impaired in the ability to achieve actual connectedness and openness; having been hurt so badly, they would appear to fear close emotional contact. In addition, the breakdown of ego boundaries suggested by the HFD, as well as the dedifferentiation process, can be expected, of course, to make relating objectively difficult.

To summarize: The underlying hypothesis that prolonged and severe stress leads to impoverishment, primitivization, and dedifferentiation seems to have found support in a good deal of the data; the price is still being paid!

INSTRUCTIONS TO AUTHORS

Style of manuscripts. Manuscripts must be prepared in the style described in the *Publishing Manual of the American Psychological Association* (2nd ed.). Instruction on tables, figures, references, metrics, and typing (all copy must be double-spaced) appear in the Manual. Authors should submit manuscripts in triplicate and should keep a copy to guard against loss.

Abstracts. Manuscripts of regular articles must be accompanied by an abstract of 100-175 words. Manuscripts of brief reports must be accompanied by an abstract of 75-100 words. All abstracts must be typed on a separate sheet of paper.

Brief Reports. The *Journal of Consulting and Clinical Psychology* will accept Brief Reports of search studies in clinical psychology. The procedure is intended to permit the publication of soundly designed studies of specialized interest or limited importance which cannot now be accepted as regular articles because of lack of space. Several pages in each issue will be devoted to Brief Reports, published in the order of their receipt without respect to the dates of receipt of the regular articles. Most Brief Reports appear in the first or second issue to go to press following their final acceptance.

An author who wishes to submit a Brief Report:

1. Sends the Brief Report, limited to two printed pages and prepared according to the specifications given below.

2. Agrees not to submit the full report to another journal of general circulation.

Specifications. The Brief Report should give a clear, condensed summary of the procedure of the study and as full an account of the results as space permits.

To ensure that a brief report does not exceed two printed pages, follow these instructions for typing: (a) Set typewriter to a 48-space line. (b) Type text. (c) Count all lines except abstracts, title, and by-line, including acknowledgments. If you have exceeded 185 lines, shorten the material. (d) If your brief report barely exceeds 75 lines (one printed page), try to edit to 75 lines exactly. Reports slightly exceeding one page will be edited for length in order to use space economically.

In Brief Reports, headings, tables, and references are avoided or, if essential, must be counted in the 75 lines. This journal no longer requires an extended report, but, if one is available, each Brief Report must be accompanied by the following footnote:

Requests for reprints and for an extended report of this study should be sent to John Doe (give the author's full name and address).

The footnote should be typed on a separate sheet and not counted in the 75-line quota.

Self-disclosure as a Function of State and Trait Anxiety

Amy L. Post and Bruce C. Wittmaier

Kirkland College

Mitchell E. Radin

Hamilton College

The influence of state and trait anxiety on self-disclosure was investigated. Debilitative and facilitative test-anxious subjects participated in a verbal learning experiment under high and low anxiety conditions. Self-disclosure was elicited by a personal information questionnaire. Subjects' responses to the questionnaire items were assessed for breadth or amount of self-disclosure and depth or intimacy of self-disclosure as well as positive-negative self-evaluation by content analysis of their statements. Results confirmed the hypothesis that individuals experiencing state anxiety disclose less than "normals." These results are discussed in light of various conceptual approaches to anxiety.

Although self-disclosure has been studied in relation to a number of personality, social, and situational variables, the effects of emotional arousal, specifically anxiety, on self-disclosure have yet to be experimentally assessed. As self-disclosure is often elicited in situations such as psychotherapy, in which anxiety may be a predominating factor, understanding the role of anxiety in self-disclosure is of considerable importance. The present study, therefore, attempts to determine the influence of anxiety on self-disclosure.

Self-disclosure has been variously defined as making yourself overt, showing yourself so that others can see you (Jourard, 1964), and the

explicit communication to others of some personal information which the others would be unlikely to acquire unless the person himself disclosed it and which is of such a nature that the individual is not likely to disclose it to everyone who asks for it. (Sermat & Smyth, 1973, p. 332)

Self-disclosure is, thus, the communication of information about one's affects, behaviors, and cognitions with the implication that the material disclosed is either secret, intimate, or emotionally charged.

The concept of self-disclosure is quite complex, since it encompasses both the qualifying of verbalizations and the assessment of the content and direction of verbalizations. Cozby (1973) has proposed that the dimensions of self-disclosure are the breadth or amount of information disclosed, depth or intimacy of this information, and the duration of time spent in disclosure. Two different parameters suggested by Chelune (1975) are the affective manner of presentation of the disclosed material and the flexibility of the disclosure pattern. In addition, other authors have focused on the positive-negative self-evaluative aspect of the content of disclosures (e.g., Sarason & Ganzer, 1962). In the present study the breadth, depth, and positive-negative aspects of individuals' self-disclosure were assessed.

The failure of self-report measures of self-disclosure to predict actual self-disclosure in situations has lead several authors to emphasize the need for behavioral assessment of self-disclosure (e.g., Chaiken & Derlega, 1974). However, there are several issues inherent in the scoring of the content of verbalizations in terms of self-disclosure that present problems. These problems include value judgments as to whether statements about feelings are more disclosing than assessed verbalizations, whether statements in

Requests for reprints should be sent to Bruce C. Wittmaier, who is now at the Lancaster Guidance Clinic, 630 Janet Avenue, Lancaster, Pennsylvania 17601.

the present tense are more disclosing than those in the past or future tenses, and whether negative information about the self is more disclosing than positive information. In addition, it has been found that the level of self-disclosure demanded by questions, modeling, or reciprocity in various situations has a profound effect on the level of self-disclosure elicited (Chaiken & Derlega, 1974; Cozby, 1973; Jourard, 1971). In light of these considerations, we have opted to measure self-disclosure by content analysis of statements made in an experimental situation with a relatively high demand for self-disclosure and to assess self-disclosure on the basis of popular consensus by using a sizable sample of raters for this analysis.

The concept of anxiety, too, is a complex one. Anxiety has been defined as "an unpleasant emotional state or condition which is characterized by subjective feelings of tension, apprehension, and worry, and by activation or arousal of the autonomic nervous system" (Spielberger, 1972, p. 482). Spielberger (1972), in attempting to clarify the concept of anxiety, makes a distinction between state and trait anxiety. He stated that "an anxiety state (A-Trait) is not directly manifested in behavior, but may be inferred from the frequency and the intensity of an individual's elevations in A-State over time" (Spielberger, 1972, p. 482). State anxiety (A-State) is thus defined by the stress level of the situation and the individual's experience of it, whereas trait anxiety (A-Trait) is defined in terms of the individual's propensity to experience state anxiety.

Much of the confusion in the anxiety literature is a result of the failure to examine separately the relationship of A-State and A-Trait with behavior (Spielberger, 1972; Wittmaier, 1974). In the present study the self-disclosure of subjects manifesting high or low trait anxiety was assessed under experimentally created conditions of high or low state anxiety.

Alpert and Haber (1960) have shown that trait measures of anxiety that are geared to specific stress situations (e.g., academic testing) have significantly better predictive validity for both manifest anxiety and performance

in those situations than do general trait measures. The Alpert-Haber Achievement Anxiety Test (AAT) is an A-Trait measure composed of two subscales that discriminate responses to anxiety, which improve performance (Facilitating subscale) from those that interfere with performance (Debilitating subscale). Scores on the Debilitating subscale correlate positively with other measures of A-Trait, whereas scores on the Facilitating subscale correlate negatively and thus reflect low A-Trait (Alpert & Haber, 1960). A useful measure of A-State is the anxiety factor of the Mood Adjective Checklist (MACL; Nowlis, 1965).

Although there have been no direct empirical investigations of the influence of anxiety on self-disclosure, research in this area with subjects characterized by other traits related to anxiety suggests that these subjects tend to disclose less than "normal" subjects. One such trait (need approval, or social desirability) may be thought of as apprehension about negative evaluation, analogous to this type of apprehension in test-anxious subjects (see Sarason, 1975). Anchor, Vojtisek, and Berger (1972) found that psychotic patients who scored extremely high on the Marlowe-Crowne Social Desirability Scale (MCSDS; Crowne & Marlowe, 1964) made a significantly lower proportion of self-statements in a group therapy session than did those scoring low or moderately high in social desirability. Anxiety over negative evaluation appeared to outweigh the tendency to comply with the demand characteristics of therapy for high-need-approval individuals. Similarly, Burhenne and Mirels (1970) found high need for approval to be correlated with low self-disclosure on five essay-type questions. Kopfsstein and Kopfsstein (1973) were unable to find a significant correlation between self-disclosure and social desirability as measured by the MCSDS, but they did find that high-need-approval subjects, as measured by other scales, were more impersonal and more evasive than their low-need-approval counterparts. Subjects with another trait related to general anxiety, uncertainty anxiety, were found to anticipate having a more superficial conversation and more per-

sonal discomfort for a subsequent conversation with an interviewer (Doster & Slaymaker, 1972). Sarason and Ganzer (1962) reported that high-test-anxious subjects presented more negative self-references than low-anxious subjects and responded to evaluative threat with increased negative self-references when asked to describe themselves prior to evaluative threat and no-threat testing.

Other evidence suggests that trait anxiety may influence self-disclosure such that the anxious individual does not modulate level of disclosure to correspond to situational demands. The anxious individual may be characterized by overly consistent patterns of self-disclosure. Chaiken, Derlerga, Bayma, and Shaw (1975) measured the self-disclosure of normal subjects and subjects high in neuroticism in response to a high- or low-disclosing confederate. These authors found a significant interaction between neuroticism and experimental condition such that the disclosure of normal subjects was considerably higher in the high-confederate-disclosure condition than in the low condition, whereas neurotic subjects maintained a moderate level regardless of condition. Finally, since communication involving self-disclosure is central to affiliative behavior, research on anxiety states and affiliation is quite relevant to the study of the effect of state anxiety on self-disclosure. Sarnoff and Zimbardo's (1961) finding that the desire for affiliation decreases with increased anxiety suggests that subjects in a high-anxiety condition will also disclose less about themselves.

It was therefore hypothesized that subjects in this experiment with higher debilitating anxiety, as well as those in a high anxiety state, would disclose less about themselves than other subjects.

Method

General Design

Subjects were identified as debilitators (high A-Trait) or facilitators (low A-Trait) using scores on the AAT. After performing a learning task under conditions designed to create high or low state anxiety, they completed a self-disclosure questionnaire. The effectiveness of the manipulations was checked using scores on the Anxiety factor of the Mood

Adjective Check List. Thus, self-disclosure could be assessed as a function of both A-Trait and A-State.

Subjects

Subjects were 48 freshmen males drawn at random from the class of 1979 at Hamilton College. Subjects were solicited by telephone to participate in a "memory experiment" and were paid for their participation.

Pretesting

The AAT (Alpert & Haber, 1960) was administered to all freshmen during orientation. The subject pool was divided between facilitators and debilitators according to scores on the AAT. Facilitators were those scoring at least 27 on the Facilitative scale ($M = 31.16$) and no more than 24 on the Debilitating scale ($M = 19.75$). Those with intermediate scores were not included in either group. Twenty-four individuals from each group participated in this study and were assigned randomly to experimental conditions. No mention of the pretesting was made 5-6 months later when the experiment was conducted.

Procedure

Each subject participated in the experiment individually. Upon entering the room for the experiment, the subject was told by the male experimenter that the study was designed as an investigation of verbal and nonverbal learning and memory.

All subjects then completed the same learning task. A list of 60 words was presented on a memory drum with a 4-sec exposure per word, and the subjects were asked to memorize these words in any manner they wished. Subjects were tested after each trial until at least 30 words were recalled. Those in the low-anxiety condition were then told that they had performed very well on the task.

At this point the procedure for the high- and low-anxiety conditions began to differ considerably. Both groups completed a digits backward task. Subjects were read increasing numbers of digits until they failed to respond accurately. The same number of digits was then repeated. Two successive failures on any number of digits were considered criterion. Subjects were then administered nine more trials, two at one digit less than criterion, three at the criterion level, and four at one digit more than criterion, in random order, for a net failure effect. Subjects in the low anxiety condition were told that the task was very difficult and not to worry about the score. After completion of the task, they were told that they had performed well. Subjects in the high anxiety condition were told that the task measured nonverbal memory and thinking ability. At the end of the digits backward task, the experimenter sympathetically inquired as to the health of

the subject, ostensibly to ascertain whether the subject had performed as well as he could have. He did not tell high A-State subjects specifically that they had performed poorly.

Subjects in the high anxiety condition were then led into a small adjacent room where a recall test for the memorized words was administered. The room had two one-way mirrors and was equipped with an intercom and a clock with a sweep second hand. The experimenter left the subject in the room after explaining how the clock worked and proceeded to give the rest of the directions over the intercom. The experimenter, in an authoritative voice, told the subject that he would have

exactly 50 seconds, no more and no less, for the next task. Your instructions for the task will be given, and then the task will be described. I will say "ready, set, begin," and then I will start the clock. When the 50 seconds are up, I will say "stop." You will immediately stop writing and raise your pen. Do not complete what you are doing and do not start anything new! Do you understand?

The subject was then instructed to put his name on the paper in front of him, but as he began to write the experimenter said "not yet" to make him aware that he was being watched by the experimenter. The subject was then instructed to turn over the paper and was told: "Now you will have 50 seconds to write down all of the words that appeared in the memory drum list. Ready! Set! Begin!"

After the recall test the subject was asked to complete the MACL (Nowlis, 1965) to assess the effectiveness of this anxiety manipulation. The anxiety scale consisted of seven adjectives (uneasy, tense, nervous, jittery, on edge, fearful, and "clutched up"), each rated on a 4-point scale, yielding scores from a low of 7 to a high of 28.

Subjects in the low anxiety condition remained in the main room after the digits backward task. These subjects were given the following instructions:

The next part of this study requires your complete cooperation and understanding. You are playing an important role in this study, since we will be using your scores as control scores. In other words, your scores will be used as the basis of comparison for other students who will be performing similar tasks but under somewhat different conditions. Try to do as well as you can, since we would like to have a realistic measure of the number of items that a person can complete in a certain amount of time. Please put your name on the top of the paper. OK? You will now have about 50 seconds to write down as many of the words as you can remember from the word list you just learned from the memory drum. Please begin and stop when I ask you to. Are you ready? All right, begin.

All of these instructions were delivered without any authoritative tone of voice. When the 50 sec had

elapsed, the experimenter told the subject to "please stop." These subjects then completed the MACL.

Self-disclosure Questionnaire

After completing the MACL following the recall test, all subjects were asked to complete a self-disclosure questionnaire and another MACL. They were then briefed on the purpose of the experiment. The self-disclosure questionnaire consisted of four questions modeled after questions rated to demand moderate to high levels of intimacy from a 40-item Self-Disclosure Questionnaire (in Jourard, 1971). Each question had a positive and a negative pole (e.g., abilities and weaknesses), so that positive and negative self-evaluation could be examined. Two forms of the questionnaire, with the arrangement of questions and positive and negative aspects of questions reversed, were administered to control for order effects. In addition, the ordering of positive and negative parts of questions was randomized within each form of the questionnaire. Subjects were given about 10 minutes to write responses to the questions. The decision as to when to terminate writing was left to the subject; the subject could write as much or as little as he chose.

The questions were presented to the subject as a possibility for the experimenter to learn significant information about the subject's personality rather than as an investigation of self-disclosure per se. The following is one form of the self-disclosure questionnaire used in this study:

Often psychological research ignores most of the experiences, feelings, and thoughts that make up an individual. We believe this leads to many oversights and oversimplifications. We are, therefore, interested in knowing more about you as a person. Please take about 10 minutes to answer the following questions as honestly as possible. Your answers to these questions will be kept strictly confidential.

1. How do you react to other people's criticism and praise of you? What things about you do people tend to criticize and praise?
2. How satisfied are you with different parts of your body, for example, weight, height, build, hair? Do members of the opposite sex find you sexually desirable?
3. What are your academic abilities and weaknesses? How do they relate realistically to your plans for the future?
4. What do you do when you feel depressed? When you feel anxious? When you feel affectionate? When you feel happy?

Breadth or amount of self-disclosure was assessed in terms of the total number of words written by each subject.

Content Analysis

Depth or intimacy of self-disclosure and positive-negative self-evaluation were assessed by content

analysis of protocols from the self-disclosure questionnaire. Subjects' responses to Question 2, the question demanding the most intimate answer as determined by independent raters, were typed in random order on 6 pages of eight statements each. Five of the six sheets were collated into a leaflet. Twenty such leaflets were prepared with all possible combinations of the six sheets to yield 16 separate ratings of intimacy and self-evaluation for each statement. The leaflet comprised a content analysis questionnaire, which was distributed to 20 upper-class college students, chosen at random who were asked to rate each statement on an intimacy and a positive-negative scale.

The intimacy, or depth of self-disclosure, of each statement was rated on a 9-point Likert-type scale from most intimate to nonintimate according to guidelines explicated in the instructions for the content analysis questionnaire. Similarly, raters were asked to assess the subjects' self-evaluations on a 9-point Likert-type scale from most positive to most negative. The following are the guidelines that raters were instructed to follow in assessing the subjects' statements:

Intimacy Scale

1. Most intimate: The person wrote things about himself that were of an extremely personal, emotional, secret, or embarrassing nature.

3. Very intimate: The person wrote things about himself that were quite personal, emotional, secret, or embarrassing, although perhaps not consistently so.

5. Somewhat intimate: The person wrote some things about himself that were personal, emotional, secret, or embarrassing, but he may have been evasive or defensive in responding.

7. Less intimate: The person generally said little about himself that was of a personal, emotional, secret, or embarrassing nature.

9. Nonintimate: The person said nothing about himself that was of a personal, emotional, secret, or embarrassing nature.

Positive-Negative Scale

1. Most positive: The person is extremely positive about himself. He is very pleased with his body and believes members of the opposite sex find him quite attractive.

3. Positive: Although he may have some reservations, the person tends to be positive about himself and appears satisfied.

5. Neutral or ambivalent: The person's positive and negative remarks about himself seem to balance or counteract each other.

7. Although the person may indicate some strong points, he appears dissatisfied or negative about himself.

9. Most negative: The person is very displeased

by his appearance and believes that members of the opposite sex are not attracted to him at all.

Results

Significant main effects for both state and trait anxiety were found on the analysis of variance of scores on the Anxiety scale of the MACL administered immediately after the recall test. A significant main effect for state anxiety was also found on the analysis of variance of scores on the Anxiety scale of the MACL administered after completion of the self-disclosure questionnaire (Table 1). Thus, after the recall test, subjects in the high anxiety condition and those with high debilitating anxiety reported experiencing moods characterized by terms like tense, nervous, jittery and on edge (i.e., anxiety). Subjects in the high anxiety condition continued to experience more of this type of negative affect after completing the self-disclosure questionnaire.

Significant main effects for both state and

trait were also found on the analysis of variance of the number of words written on the self-disclosure questionnaire, the measure of the breadth of self-disclosure. As predicted, subjects in the high anxiety condition and those with greater debilitating anxiety wrote significantly fewer words on the questionnaire (Table 2). Intercorrelations of the number of words written per question were significant for all but one comparison. Eight out of nine of these were significant at or beyond the .001 level, indicating a high degree of consistency in each subject's response to the questionnaire and a high reliability for the measure.

The analysis of variance of the depth of self-disclosure as rated on the intimacy scale of the content analysis questionnaire yielded a significant main effect for state. Subjects in the high anxiety condition were seen to have disclosed less intimately about themselves than their control counterparts. There was no significant main effect for trait on this measure nor any interaction effect (Table 3). A Pearson correlation of .75 ($p < .001$) was

found for the split-half interrater reliability on the intimacy scale.

There was no significant main effect on the positive-negative scale of the content analysis questionnaire (Table 4). The State \times Trait interaction approached but did not attain significance, $F(1, 44) = 2.23$, $p < .13$, two-tailed. The split-half interrater reliability was .93 ($p < .001$). Subjects with high facilitating anxiety tended to express more positive self-evaluations in the low anxiety condition than the control condition, whereas subjects with high debilitating anxiety tended to express more positive self-evaluations in the experimental condition than in the control.

Discussion

The effectiveness of the situational cues of the high anxiety condition to elicit state anxiety was borne out by the difference of scores on the Anxiety scale of the MACL completed after the recall test. Those in the high anxiety condition did, in fact, report more anxiety than did those in the control condition. In both conditions subjects with high debilitating test anxiety reported experiencing more anxiety than facilitators. This result gives credence to Spielberger's contention that trait anxiety, in this case debilitating test anxiety, can be operationalized as the propensity to experience state anxiety with greater frequency or intensity, even in relatively innocuous testing situations like the control con-

Table 4

dition. Subjects in the high anxiety condition reported experiencing more anxiety than controls even after the self-disclosure questionnaire was administered, though now there were no differences between debilitators and facilitators. This result may be viewed as supporting the notion of the highly situation-specific nature of the trait, debilitating test anxiety.

As predicted, high state anxiety resulted in less breadth of self-disclosure as well as less intimate disclosure. Spence and Spence (1966) have theorized that anxiety functions to activate dominant responses that have a high degree of habit strength. The lower self-disclosure of subjects in the high anxiety condition thus follows, in that introspective, personal, emotional statements are certainly not the most salient responses in a testing situation. Indeed, the physiological arousal involved in the "fight or flight" response (Selye, 1956) seems antithetical to introspection. Sarason (1975) noted, moreover, that the internal focus of attention of high-test-anxious subjects (A-Trait) leads to failure to attend to external task-relevant cues. In the present study, those in the high anxiety condition, who reported experiencing greater anxiety than controls both before and after completing the self-disclosure questionnaire (and to some extent debilitators in the control condition), may well have been attending to their present arousal state. As a result, perhaps, of this internal focus of attention, they failed to attend to information about them-

selves that was relevant to the self-disclosure questionnaire.

Although debilitators in both conditions did produce less disclosure quantitatively, no difference was seen in the intimacy with which debilitators and facilitators wrote about themselves. As noted above, the debilitators in the control condition experienced lower anxiety than those in the high anxiety condition. Their intermediate level of arousal may have functioned to moderate the number of words they wrote but not their overall intimacy. Working on the self-disclosure questionnaire may have served to moderate the anxiety experienced by debilitators. As intimacy was rated on the basis of responses to the second question (on the alternate form, the third), responding to the preceding question(s) may have served to dissipate anxiety and, consequently, to increase intimacy. Although there has been no empirical demonstration that self-disclosure once elicited functions to ameliorate state anxiety, the finding that self-disclosure is greater in a prolonged stress condition than in a control situation (Altman & Haythorn, 1965) suggests that self-disclosure may serve to reduce anxiety.

The lower intimacy of self-disclosure of subjects in the high anxiety condition may have been, above all, a function of the evaluative threat involved in disclosing intimate information about the self in this particular situation. The anxiety manipulation used in this experiment pivoted on inducing threat to self-esteem by making tasks like the digit span ego involving and creating a failure experience. Although, contrary to expectations, this threat did not manifest itself significantly in the subject's self-evaluations, it may have been crucial in the lower self-disclosure of those in the high anxiety condition. Indeed, low levels of disclosure would seem to function to protect the individual from threat to his most secret or emotionally charged behavior, affect, and thought, especially when this threat is a salient feature of the situation. That debilitators in the control condition did not differ from facilitators in the intimacy of their self-disclosures again suggests that they did not discriminate the self-disclosure questionnaire as a threatening stimu-

lus, whereas the recall test was obviously anxiety evoking for debilitators, again supporting the notion of the situation-specific nature of debilitating test anxiety.

Although this experiment has shown that state anxiety arising from both situational cues (A-State) and the individual's propensity to experience anxiety (A-Trait) results in both lower breadth and depth of self-disclosure, much more empirical work is needed on the relationship of anxiety to self-disclosure. For example, Would the pattern of findings be similar to those of the present study if verbal, rather than written, self-disclosure were used (Anonymous reviewer, Note 1)? Understanding this relationship is crucial to developing effective psychotherapeutic interventions for anxious patients as well as for understanding social maladjustments and their consequences for anxious individuals. Although this experiment did attempt to assess the effect of anxiety on self-disclosure, it did not assess the effect of self-disclosure on anxiety. If self-disclosure does aid in coping with anxiety, as was suggested previously, then inducing anxious subjects to self-disclose in an appropriate situation should lower their level of anxiety. This point, too, needs to be investigated.

Effectiveness of Widows' Groups in Facilitating Change

Carol J. Barrett
Wichita State University

Seventy urban widows participated in one of three group treatments for a 7-week period or a waiting list control group. Two therapists each led a self-help group, a "confidant" group, and a women's consciousness-raising group. Personality, attitude, and behavioral measures were obtained at pretest, posttest, and at a 14-week follow-up. At posttest, subjects in *all* conditions had significantly higher self-esteem, experienced a significant increase in intensity of grief, and espoused significantly more negative attitudes toward remarriage. Experimental subjects showed significant improvement in their ratings of future health and became significantly less other-oriented in their attitudes toward women relative to the controls. The therapist variable produced few differences in response to treatment. At follow-up, treatment gains were maintained. Life changes were significantly more positive in the women's consciousness-raising groups, and posttest evaluations of the program by these subjects were significantly higher. All treatments resulted in high rates of contact among participants in the group.

Research has demonstrated amply that widowhood is a stage in the life cycle during which multiple stresses occur. The degree of change in one's life necessary for adjustment to the spouse's death is deemed greater than that required for 42 other major life events (Holmes & Masuda, Note 1). There is strong evidence that widowed persons experience impairment in both mental and physical health relative to married persons of the same age (Barrett, 1977). Psychiatric symptoms (Clayton, 1974; Parkes, 1964), mental illness (Bel-

lin & Hardt, 1958), inception of psychiatric outpatient and inpatient services (Robertson, 1974; Stein & Susser, 1969), and suicide (Bock & Webber, 1972; Cosneck, 1966; Segal, 1969) are all more frequent among the widowed than the married.

Disabling illness (Woolsey, 1952) and hospitalization for medical problems (California Department of Public Health, 1958; Rosenfeld, Katz, & Donabedian, 1957; Rosenfeld, Mott, & Taylor, 1951) are also more frequent among the widowed. Physical symptoms were more prevalent among young widows relative to married women (Maddison & Viola, 1968; Parkes & Brown, 1972) but not among the elderly widowed group (Heyman & Gianturco, 1973). In a landmark study, Kraus and Lilienfeld (1959) documented higher death rates among both black and white widowed persons of both sexes, for all age groups and for all causes of death, when compared to married persons of similar age and socioeconomic status. The discrepancy in death rates between widowed and married persons was largest at the younger levels.

There are convincing arguments that such differences in the level of functioning of same-age married and widowed individuals cannot

This article is based on the author's doctoral dissertation research at the University of Southern California in 1974. A report of the preliminary findings was made at the Gerontological Society Meeting in Miami Beach, Florida, in 1973 (*The Gerontologist*, 13, p. 66).

The author appreciates the comments of Jim Birren during the formulative stage of this research, the suggestions of Al Marston during its execution, and the cooperation of members of the Institute of Lifetime Learning in Long Beach, California, who participated in the pilot study. Lisa Pomeroy served as one of the group therapists, and Elwin Barrett and Sally Daniel assisted in the data analysis.

be accounted for totally by predisposing characteristics operative prior to marriage, the effects of a shared unfavorable environment, artifacts in reporting procedures, and the possibility of higher remarriage rates by the healthy widowed (e.g., Parkes, Benjamin, & Fitzgerald, 1969; Stein & Susser, 1969). With an occasional exception (Lowenthal, 1964), widowhood has been shown to increase social isolation (Adams, 1968; Berardo, 1970; Marris, 1958). In Lopata's (1973) extensive study of 301 widows over age 50 in the Chicago area, as well as in other research (Nuckols, 1973), loneliness was indeed perceived as the worst problem. A substantial proportion of widowed persons must assume the additional responsibility of single parenthood. (Widows constitute the largest group of single parents; Schlesinger, 1971.) Financial problems are often severe (Nuckols, 1973; Palmore, Stanley, & Cormier, 1963), and legal problems complicate the resolution of grief that must proceed with little institutionalized support (Gorer, 1965). The available evidence, the stress theory of mental illness (e.g., Simon, 1970) and of physical illness (Holmes & Masuda, Note 1), and the application of social role theory to widowhood (Lopata, 1973) support the hypothesis that the experience of widowhood itself may produce the observed physical and emotional distress.

The importance of this position is highlighted by the size of the population currently and potentially at risk. The 12 million widowed persons in this country already number almost 5% of the total population (U.S. Bureau of the Census, 1970). The projected increase in the size of the older population enhances the probability that the proportion of widowed persons will continue to increase. The probability of widowhood is much higher for women, who usually marry men older than themselves, despite the fact that they outlive men by 7-8 years. Approximately three out of four married women will become widows (Lewis & Berns, 1975). Currently there are more than four times as many widows as widowers. Widowhood is seldom a brief episode at the end of the life span; the average duration of widowhood for widows who do not

remarry and who die from natural causes is 18½ years (Carter & Glick, 1970).

In recognition of the special needs of the widowed, the high-risk nature of this group, and the dearth of responsive programming in traditional mental health agencies (Silverman, 1966), a variety of therapeutic programs have recently been developed by mental health professionals (Abrahams, 1972; Miles & Hays, 1975; Silverman, 1970; Woods, 1973; Antoniak, Note 2; Van Coevering, Note 3; Parkes, Note 4) and by lay organizations (e.g., NAIM, a Catholic-sponsored organization; THEOS (They Help Each Other Spiritually), a nondenominational organization based in Pittsburgh; and American Association of Retired Persons' Widowed-to-Widowed Program). Most utilize widowed paraprofessionals and offer individual help to the recently widowed; others arrange discussion groups. Unfortunately, controlled outcome studies of such innovative programs are nonexistent.

The present study sought to develop and evaluate three different therapeutic group interventions for widowed women and to compare the results of treatment to a waiting list control group. Although the propensity of widowhood is higher among older women, research suggests that stresses may be greater for younger widows (Kraus & Lilienfeld, 1959; Parkes, 1964; Robertson, 1974). Hence, the treatment groups were designed to respond to the needs of widows of all ages. Since many of the social and economic stresses of widowhood persist long after the husband's death, no limit was set on the duration of widowhood for participants in the study.

A basic premise in all three treatment groups was that widowed women would be able to help each other cope with the stresses of their situation (Silverman, 1970). The design of each treatment reflected a different research base or theoretical posture. The possible superiority of self-help strategies in comparison with traditional psychotherapy among groups with pervasive common problems (e.g., Hurvitz, 1970) provided a basis for the self-help groups. The advent of peer counseling methods and the research of Lowenthal and Haven (1968) provided the rationale for the

confidant groups. These investigators have shown that older persons who have a confidant have better subsequent mental health than those without one. Since many widows will have lost a primary confidant in their husbands, the development of a compatible widow confidant might be therapeutic, particularly in light of Lopata's (1973) analysis of the difficulties that widows have in making new friends. The advent of the consciousness raising group in the women's movement provided a model for the widows' *consciousness raising* groups. Although consciousness raising groups enjoy immense popularity and personal accounts of their helpfulness to women abound, little systematic research has accompanied them. Since a number of the stresses of widowhood derive from sex roles operative both in marriage and subsequently, a group experience focusing on sex roles was considered to have potential therapeutic value to widows. Since there were no previous outcome studies to guide the selection of dependent variables relevant to widowed persons' services, a variety of potentially useful measures was included.

Method

Subjects

Two hundred and thirty-nine widows who responded to a news item in the *Los Angeles Times* or one of six Los Angeles area newspapers that briefly described the program were invited to an orientation meeting. (Eighty-one subsequent inquiries were referred to local community mental health centers.) One hundred and twenty-six attended. Of these, 83¹ (66%) participated in the program. Ten out of 28 subjects randomly assigned to the waiting list control group, and 25 out of 86 assigned to treatment did not return. Eight subjects who could not participate immediately due to prior commitments were permitted to join the waiting list group (4 did so), but their data were omitted to prevent confounding of subject characteristics with control group status. Eight subjects in the treatment groups who attended fewer than four of the seven sessions (4 confidant subjects, 2 self-help subjects, and 2 consciousness raising subjects) were dropped from the analysis along with 1 control subject later identified as a divorcee. This left a total of 70 subjects, including 17 controls and 53 assigned to treatment groups.

The subjects ranged in age from 32 to 74, with a mean age of 55.7 ($SD = 9.2$ years). The duration

of widowhood ranged from less than 1 month to 22 years, with a mean of 4 years 9 months and median of 3 years 9 months. Subjects widowed 2 years or less comprised about one third of the sample. Ten subjects had been widowed over 10 years. The majority (87%) had been married only once. About a third still had children at home. Twenty-eight were Jewish; 23, Protestant; 10, Catholic; and 9 indicated some other religious category. Fifty-three percent were employed, 30% were retired or not employed by choice, and 17% were unemployed. More than 70% of the sample had at least some college education, and 16% had a graduate or professional degree. The modal current monthly income from all sources was \$600-\$900; the modal household income prior to widowhood was over \$1,500 a month.

Procedure

Each subject attended one of four orientation meetings, which began with a brief lecture on widowhood. They were told that they would be attending one of three types of discussion group focusing on "specific problems of widowhood" (the self-help groups), "the development of friendships" (the confidant groups), or "the roles of women in society" (the consciousness raising groups). Subjects completed demographic information and the pretest dependent measures and indicated their availability for meeting times (without knowledge of which group would meet at which time). A \$15 check payable at the first group session and to be returned at follow-up was required to reduce subject attrition.²

All subjects who attended orientation (except for those who withdrew) were assigned as randomly as possible to one of three treatment conditions or to a waiting list control group. Several factors prevented complete random assignment. The first was a limitation on the availability of subjects. No subject was assigned to a group that it was impossible for her to attend. To prevent confounding of subject characteristics such as employment status with treatment, one group of each of the treatments met on a weekday, and one met on Saturday.

A second factor was the desirability of pairing confidant group subjects with someone who lives nearby to increase the likelihood of continued relationship.

¹ Inquiries were received from all over Los Angeles County. Phone calls from a number of potential subjects hoping for a neighborhood group suggested that the attendance at orientation and the reduced number of actual participants were in part a reflection of the excessive travel time required in the city.

² Informal feedback suggested that this procedure may have backfired. Some potential subjects who attended orientation but did not subsequently join a group may have been deterred by the fee. Several had no checking account.

tionships posttreatment. To ensure geographic proximity, confidant group assignments were made from among the two most heavily represented of the five toll-free Los Angeles County regions designated by the telephone company. Subjects in one group all resided in the San Fernando Valley; subjects in the other group lived in the central city area. (Additional subjects from these regions were assigned to other treatment conditions.)

The third factor was the desirability of beginning the groups as soon as possible after orientation to reduce the likelihood of attrition. Subjects from the first orientation meetings were assigned to the first therapist or the control group; subjects from the final meetings were assigned to the second therapist or the control group. The final number of subjects in each group appears in Table 1.

All experimental subjects began a 7-week treatment group within 1-2 weeks of orientation. Approximately 14 weeks after the posttest (13-15 weeks), and 6 months after the program announcement, all subjects attended a follow-up session. After completion of data forms, the preliminary results of the study were described. Control subjects participated in a treatment group following the collection of posttest data and hence were omitted from the follow-up analysis.

All groups met for 2 hours once a week for 7 weeks at the University of Southern California. Two (nonwidowed) female doctoral students in clinical psychology each led one of three different groups pretested in a pilot study. The purpose of the self-help groups was to encourage participants to help each other find solutions to the problems of widowhood. These groups were told that widowed persons are the experts on widowhood. The therapist's role was to facilitate discussion; all direct requests for advice were referred back to group members, and reticent members were encouraged to share their experiences. The therapist praised group members when specific suggestions were offered to others. The problems discussed were those initiated by the members themselves and included loneliness, grief, single parenting, reduced financial resources and employment difficulties, decisions about living arrangements, strained relationships with relatives and married friends, new relationships with men, and legal problems.

The purpose of the confidant groups was to facilitate the development of a close friendship between pairs of widows. Subjects were paired for the duration of the group in one of two ways. At the close of the first group discussion,³ subjects could confidentially indicate preferences for pair assignments. Those who did not wish to make this decision were assigned primarily on the basis of matched age and duration of widowhood. The group format consisted of an intimacy training task in pairs, during which the therapist moved from pair to pair as needed, followed by a discussion of the experience by the whole group. The intimacy tasks were arranged in gradually increasing difficulty over the 7-week period; they proceeded from a request to

find three things the pair had in common to a request to share personal problems and to make an explicit offer of help to one's confidant.

The purpose of the consciousness raising groups was to facilitate the participants' awareness of how their experiences as widows relate to them as women. The group structure was modeled after that developed by the Consciousness Raising Committee of the Los Angeles chapter of the National Organization for Women (Freeman, Note 5). Each group was given a list of possible sex role topics of particular relevance to widows⁴; the group selected the topic to be discussed 1 week in advance. Each session consisted of (a) introductory comments about the topic from the leader's own experience, (b) 5-10 minutes for each member in sequence around the group to express her reactions to the topic without interruption, and (c) open discussion by all participants. "No confrontation" was an enforced rule. Members could ask questions after the individual reactions but were not permitted to make comments until their "turns."

Measures

Eighteen personality, attitude, and behavioral measures were obtained by written self-report; 12 at pretest, posttest, and follow-up; 2 at posttest and follow-up; and 4 at follow-up only (see Table 2). Ten measures, comprised of 6 rating instruments and 4 behavioral indices, were developed by me to assess physical, emotional, and social functioning in widowhood.⁵ These included the frequency of phys-

³ The announced beginning topic in all groups was the question of whether widows or widowers experience greater stress. However, both therapists observed that the actual primary topic was the circumstances of the husband's death, often tearfully recounted. A similar phenomenon occurred in Lopata's interviews (Note 7).

⁴ Available from the author on request. Popular topics included: "Does widowhood oppress women?" and "Are you still a wife?"

⁵ Copies of instruments not previously published are available from the author.

cal complaints (summed across six ailments that are common in bereavement), a prediction of one's health in 5 years (poor, fair, good, and excellent were assigned scores of 1-4, respectively), intensity of grief (a sum of 12 7-point rating scales assessing feelings of loneliness, inability to cope, sorrow, guilt, anger, and depression), attitudes toward widowhood and remarriage (2 7-point scales), and social role involvement (sum of ratings representing involvement in eight major social roles). A major behavioral measure was the quality of life change since enrollment in the program; responses to an open-ended follow-up question were rated independently on a 5-point scale from extremely positive to extremely negative by two persons blind with respect to treatment condition. Responses were also content analyzed. Additional behavioral measures permitted an evaluation of the extent of social activity among members of the various groups subsequent to treatment. These were the number of spontaneous group meetings during the follow-up period, the number of group members contacted individually, and the total number of individual contacts during follow-up.

Three personality variables were included: Rosenberg's (1962) self-esteem measure; Rotter's (1966) Internal-External Locus of Control (I-E) Scale; and Neugarten, Havighurst, and Tobin's (1961) Life Satisfaction Index A; as well as three measures of attitudes toward women; a 15-item radical versus

conservatism scale adapted from Spence and Helmreich (1972); and Gump's (1972) other-orientation and self-orientation measures. Other-orientation is a composite of three factors representing the views that identity is derived through traditional roles, that woman's role is submissive, and that home orientation and duty to children should be stressed. Self-orientation is a composite of four factors reflecting a need for individualistic achievement and satisfactions, a sense of autonomy and heightened independence, and the beliefs that the traditional role implies some relinquishing of needs for personal fulfillment and that the family is inadequate to completely fulfill one's needs. At posttest and follow-up, subjects evaluated the degree of help received from the group and the degree to which they learned from the group on 7-point scales.

Results

Pretest

Multivariate and univariate analyses of variance performed on the 12 pretested dependent variables resulted in no significant differences between the four conditions (self-help, confidant, consciousness raising, and control groups) at the start of treatment. Nor was there any difference in the average age or duration of widowhood among subjects in the four conditions.

Posttest

To determine whether treatment groups could be combined across therapists, a multivariate analysis of variance and univariate analyses of variance were performed on the pre-post change scores for the six available widowhood functioning variables and the three personality variables, with therapist (two levels) and treatment (three levels) as independent factors. The only significant therapist effect was for attitude toward remarriage, $F(1, 40) = 6.44$, $p < .05$ (see Table 3), and none of the therapist-treatment interactions was significant. Similarly, tests for therapist and therapist-treatment interaction effects on the attitudes toward women change scores were not significant.

Hence, one-way (four-level) multivariate analyses of variance were performed on the pre-post change scores for the nine personality and widowhood functioning variables, and separately for the three attitudes toward

women variables, on all subjects (including the control group) for whom data were complete. The degrees of freedom in the treatment factor were partitioned to enable planned comparisons to assess (a) whether any significant change occurred in the variables from pretest to posttest, (b) whether the change among experimental subjects differed from the change among controls, and (c) whether there were any between-treatment differences in the change scores.

Both multivariate tests for pre-post change across all subjects were significant, $F(9, 51) = 3.09$, $p < .005$, $F(3, 60) = 4.20$, $p < .01$. Subsequent univariate tests revealed a highly significant increase in self-esteem, $F(1, 59) = 14.07$, $p < .001$, a significant increase in the intensity of grief, $F(1, 59) = 9.92$, $p = .003$, significantly more negative attitudes toward remarriage, $F(1, 59) = 8.07$, $p = .006$, a significant reduction in other-oriented attitudes toward women, $F(1, 62) = 7.50$, $p = .008$, and an almost-significant increase in self-orientation ($p = .07$). The mean changes in these variables by treatment appear in Table 3.

Although neither multivariate test of experimental-control group differences was significant, two univariate tests were significant. Experimental subjects showed a more positive change in their 5-year health predictions, $F(1, 59) = 4.12$, $p < .05$, and became less other-oriented than controls, $F(1, 62) = 3.86$, $p = .05$. Treatment means for these variables appear in Table 3. Scrutiny of the group means revealed that the significant reduction in other-orientation across all subjects was

totally accounted for by the substantial change among experimental subjects. There were no significant between-treatment differences on any of the 12 pre-post variables.

A 3×2 multivariate analysis of variance on the two posttest experimental group evaluation measures yielded a significant main effect for treatment, $F(4, 92) = 2.62$, $p < .05$, and no therapist effect or Therapist \times Treatment interaction. Both extent of help from the group, $F(2, 47) = 4.05$, $p < .05$, and extent of learning in the group, $F(2, 47) = 5.03$, $p < .01$, varied with the treatment. Table 4 presents the mean evaluation scores by treatment. The highest ratings on both variables occurred in the consciousness raising groups and the lowest in the self-help groups.

Follow-up

A one-way (three-level) multivariate analysis of variance and univariate analyses of variance on the change scores from pretest to follow-up of the experimental subjects for whom complete data were available on the nine pretested widowhood functioning and personality variables still did not yield any significant differences among the three treatments, but the multivariate test for non-zero change from pretest to follow-up was highly significant, $F(10, 32) = 3.79$, $p = .002$. Univariate tests indicated that experimental subjects maintained the significant increase in self-esteem, $F(1, 41) = 18.98$, $p < .001$, and in intensity of grief, $F(1, 41) = 23.7$, $p < .001$, and also maintained their more negative

Table 3
Mean Pre-Post Change in Selected Variables

Variable	Consciousness raising	Confidant	Self-help	Control

Follow-up	5.85	5.57	4.70

attitudes toward remarriage, $F(1, 41) = 6.94$, $p < .05$. A trend toward increased social role involvement by follow-up was also observed ($p = .08$). Mean changes by treatment are reported in Table 5.

Although differences between treatments did not occur in the change in attitudes toward women from pretest to follow-up among the experimental subjects for whom complete data were available, here again an almost significant change across groups emerged in the multivariate analysis of variance ($p < .07$; see Table 5 for the mean changes in these variables by treatment). The univariate test of change in other-orientation was significant, $F(1, 45) = 5.57$, $p < .05$; at follow-up, subjects held less other-oriented attitudes.

The 3×2 multivariate test of the two group evaluation variables at follow-up did not yield a significant main effect for treatment, although the lowest ratings were still given by the self-help participants and the highest by consciousness raising participants.

Table 5
Mean Change from Pretest to Follow-up in Selected Variables by Treatment

Variable	Consciousness raising	Confident	Self-help
Self-esteem	4.71	3.18	4.56
Intensity of grief	6.65	9.46	6.13
Health prediction	.11	.09	-.06
Attitude toward remarriage	-.88	-.55	-1.13
Social role engagement	1.24	1.64	2.44
Other-orientation	-.61	-1.21	-1.81
Self-orientation	1.00	1.29	-.50
Radical versus conservative attitudes toward women	.28	2.00	-.06

The treatment effect was significant in the univariate test of extent of help from the group, $F(2, 45) = 3.38$, $p < .05$. Group means are reported in Table 4. Examination of the group evaluation means and standard deviations suggested that the reduced level of significance of treatment at follow-up was attributable to the increased variance in rating in almost all cells, rather than to a convergence of treatment means. As in the posttest analysis of these data, the therapist and therapist-treatment interaction effects were not significant.

A 3×2 multivariate analysis of variance was performed on the four behavioral measures obtained at follow-up on the experimental subjects for whom complete data were available. The main effect for treatment was significant, $F(8, 84) = 3.14$, $p < .005$, and were the main effect for therapist, $F(4, 42) = 3.47$, $p < .05$, and the therapist-treatment interaction, $F(8, 84) = 4.45$, $p < .001$. Group means for these variables appear in Table 4.

Univariate tests yielded a significant treatment effect for both quality of life change, $F(2, 45) = 3.36$, $p < .005$, and number of group members contacted, $F(2, 45) = 7.03$, $p < .005$. Pearson's correlation of life change scores by the two raters was .89 ($p < .001$). The most positive life changes occurred in the consciousness raising groups, and the least positive changes, in the self-help groups. The content analysis of the types of reported changes across all subjects appears in Table 7. Changes occurred in all spheres of living (except religion) but predominated in the area of mental health. The most frequently

Table 6
Group Means for Behavioral Measures at Follow-up

Variable	Therapist	Consciousness raising	Confidant	Self-help
No. persons contacted	1	1.82	4.12	.43
	2	1.33	.50	.80
No. contacts	1	2.82	13.00	22.57
	2	5.33	1.00	1.50
Group meetings	1	.82	1.25	.14
	2	.00	.00	.90
Life change	1	4.09	2.88	3.14
	2	4.44	4.17	3.40

reported changes were reduced feelings of unique experience; increased self-confidence; more positive future outlook; the incorporation of help from the group; increased social contacts; return to school; and on the negative side, contraction of personal illness. On the average, confidant subjects contacted the most group members; self-help subjects contacted the fewest. At follow-up, four of the six treatment groups planned to continue meeting on their own.^a

Univariate tests on the behavioral measures substantiated the multivariate therapist effect. Both number of members contacted, $F(1, 45) = 6.97$, $p < .01$, and total number of contacts, $F(1, 45) = 4.87$, $p < .05$, varied with the therapist. Subjects in more of the first therapist's groups had higher rates of contact during follow-up. (Because of the differential starting dates, these groups had a 2-week longer follow-up.) Univariate tests for the therapist-treatment interaction were significant for the number of members contacted, $F(2, 45) = 8.04$, $p < .001$, and the number of spontaneous group meetings, $F(2, 45) = 5.4$, $p < .01$, and a trend occurred for total number of contacts ($p = .06$). Examination of the group means revealed that discrepant outcomes occurred in the two confidant groups. One therapist's group members experienced the highest levels of follow-up contact in this treatment; the other's experienced the lowest levels here.

Discussion

The comparison of groups at the pretest indicated that an approximation of random

assignment of subjects was achieved. The treatment groups were somewhat successful in facilitating greater change than that experienced in the control group. Experimental subjects were more likely to give up the view that others' needs are more important than their own. That this change was not limited to consciousness raising participants suggests that a group experience provided a new reference group of widowed women that facilitated new norms that were competing effectively with married group norms in the population. This may be one advantage of group as opposed to individual interventions with the widowed.

The more positive health predictions among experimental subjects is particularly noteworthy in light of the known physical impairment of the widowed (and the actual illness of several subjects), the fact that no medical intervention was offered, and the fact that this significant difference was based on change in a 4-point scale. The index of actual physical complaints did not change, perhaps because the ailments addressed in this variable all commonly occur early in bereavement, whereas many subjects had been widowed for relatively long periods of time. Or perhaps the change in prediction of future health is better understood as an indication of morale. Dunkle (Note 6) found that changing health was related to a change in morale among elderly women but not among elderly men. Parkes (1970) claimed that widows'

^a Subsequent correspondence documented that these plans were carried out.

global self-reports of *current* poor health were related more to feelings of anger and irritability than to physical symptoms per se, although data were not presented to document this finding.

The treatment groups also were successful as catalysts for social interaction from pretest to follow-up. High rates of contact among group members were generated. Treatment plans for continued meetings even after follow-up attest to the program's effectiveness in providing an antidote to loneliness.⁷ Psychotherapy outcome studies seldom include extensive follow-up, and when they do, results are often discouraging. Yet in this study, treatment gains were maintained for several months.

The simultaneous gains in self-esteem and intensity of grief merit discussion. Widowed persons frequently complain that others are unwilling to listen to their negative feelings. Unfinished "grief work" (Caplan, 1964) may be common in this population, despite years of widowhood. Supported by a group of peers, there may be nothing contradictory about the simultaneous expression of grief and increased positive regard for oneself. It is possible that the increased intensity reported reflects a new acceptance of negative emotional reactions to widowhood and a lessening of their denial. In any event, the apparent increase in grief amidst an array of other positive changes casts doubt on the rationale of treatment modalities for widowed persons that focus primarily on the *reduction* of feelings of sorrow, anger, depression, guilt, and so on.

Of the three types of widows' groups pioneered in this research, the most consistently effective method was the widows' consciousness raising group, and treatment outcomes were remarkably similar across therapists. The high degree of structure in the consciousness raising groups, which guaranteed opportunity

⁷ In this regard, it is interesting that a particular task of the confidant groups presumed to require a fairly high level of intimacy—the sharing of telephone numbers in order to plan a mutual activity outside the group—became redundant, as telephone numbers were spontaneously exchanged by almost all groups by midtreatment.

nities for all members to participate actively, may have contributed to their success. Alternatively, the content of these groups may have been particularly therapeutic. The focus on women and sex role oppression provided a natural external target for anger. This emotion has long been observed to be facilitative in the treatment of depression.

The self-help format on the whole was least effective, although no between-treatment differences emerged on a number of variables reflecting positive change. Most self-help groups do not have a professional leader. It is possible that the presence of a therapist in these groups was counterproductive, despite, or perhaps because of, her limited role.

Response to the confidant groups was more variable. Both therapists found these groups the most difficult to lead, as departures in the session plans were often necessitated by absences or by a discussion of the members' objections. The very idea of becoming particularly well acquainted with only one widow appeared to foster apprehension. (The average confidant subject in fact contacted *more* members during follow-up than subjects in either of the other treatments.) The confidant group strategy might be more effective if limited to widows who have *no* confidant prior to treatment.

A major finding of this research was that substantial change occurred in *all* groups including the control group. The promise of an extended small group experience in 2 months time may itself have had a therapeutic effect on the waiting list controls, especially in view of the reduced opportunities for social interaction and the scarcity of helping resources in widowhood. This interpretation is consistent with my clinical observation that an enthusiastic, eager quality in the initial meeting of the waiting list discussion group replaced the more depressive tone in the initial meetings of the earlier groups. It may be worthwhile to explore the potential therapeutic benefits of waiting periods with other clinical populations.

The gains of the control group may also reflect a positive change bias in those who tolerated the waiting period and returned. However, this is unlikely as a total explanation,

since the percentage of control subjects who did not return (35.8%) is not that different from the percentage of subjects assigned to a treatment group who never attended (29%). It could also be argued that waiting list subjects who improve on their own should be *less* likely to return for treatment.

Attention should be addressed to the subject characteristics that increase the probability of enrollment in a therapeutic program for widows and those that are associated with the greatest therapeutic impact. The fact that widows of all ages and duration of widowhood enrolled in the program refutes the views that the stresses of widowhood are limited to a particular age group and that only the recently widowed need help. Clearly, the strategy of placing widows varying widely in age and duration of widowhood⁸ in the same group was not a hindrance to the program's effectiveness, and it may have been facilitative. Experienced widows probably functioned as role models for the newcomers, and the diversity of the members probably served to remind the widow of available options in her own life-style decisions.

Compared to widows nationally, subjects in this research overrepresented the Jewish faith, high educational achievement, and prior upper-income status. The location of the program on a university campus and the required fee may have contributed to the observed sample bias. The generalizability of the results awaits replication with other widowed samples.

A number of dependent variables in this research did not evolve as effective descriptors of the personal changes that accompany participation in a social service for widows (locus of control,⁹ life satisfaction, frequency of physical complaints, attitude toward widowhood, and the subset of items from the radical versus conservative Attitudes Toward Women scale). Some of the measures may have been too global to reflect the changes

⁸ Few extremely recent widows participated.

⁹ The I-E scale may have limited applicability to an elderly population. Subject complaints about the irrelevance of items were common.

that occurred. Subsequent research might focus on the discrete types of life changes reported by subjects on the open-ended question, that is, the feeling of unique experience, attitude toward the future, self-confidence, extent of social contacts, and so on.

This research has addressed the question of how best to facilitate therapeutic change among widows using a group format. It provides the best documentation to date that psychological and social change can be fostered by innovative programs for the widowed. Mental health professionals as well as widowed persons should be able to assume an attitude of hopefulness instead of resignation with respect to the circumstances of widowhood. Some subjects experienced far-reaching changes in several areas of their lives during the 6 months from the time they read about the program to the follow-up after their small group experience. A question for the future is how to predict which persons will profit most from a widows' group.

Reduction of Test Anxiety Through Cognitive Restructuring

Marvin R. Goldfried

State University of New York at Stony Brook

Marsha M. Linehan and Jean L. Smith

The Catholic University of America

This collaborative clinical outcome study compared two procedures for reducing test anxiety with a waiting list control. In the first, systematic rational restructuring, participants were trained to realistically reevaluate imaginatively presented test-taking situations. In the second, a prolonged exposure condition, the same hierarchy items were presented but with no instructions for coping cognitively. On the basis of questionnaire measures of test anxiety, greater anxiety reduction was found in the systematic rational restructuring condition, followed by the prolonged exposure group, with no changes for the waiting list control. Only those in the rational restructuring condition reported a significant decrease in subjective anxiety when placed in an analogue test-taking situation. Participants in the restructuring condition also reported greater generalized anxiety reduction in social-evaluative situations. Within the broader context of cognitive behavior therapy, the results of the present investigation add to the increasing number of outcome studies indicating that the cognitive reappraisal of anxiety-provoking situations can offer a markedly effective treatment procedure for the reduction of anxiety.

The incorporation of cognitive variables within behavior therapy represents a clear and unmistakable trend. Much of the current work in this area has been based on the clinical observation of Ellis (1962), who has argued that modification of inappropriate expectations and beliefs could lead to behavior change. Until recently, however, Ellis' rational-emotive therapy had relatively little impact on the behavioral movement. The difficulty of fitting Ellis' approach into a behavioral orientation has been due, in part, to

the lack of clear therapeutic guidelines as well as to the absence of an empirical data base for its clinical effectiveness. This situation is clearly changing, and steps are currently being taken to incorporate many of Ellis' concepts and procedures into the field of cognitive behavior therapy (Beck, 1976; Goldfried & Davison, 1976; Goldfried, Decenteeo, & Weinberg, 1974; Mahoney, 1974; Meichenbaum, 1977). A number of outcome studies have appeared in the literature, demonstrating that speech anxiety (Meichenbaum, Gilmore, & Fedoravichous, 1971; Trexler & Karst, 1972), interpersonal anxiety (DiLoreto, 1971; Kanter & Goldfried, Note 1), unassertive behavior (Thorpe, 1975; Wolfe & Fodor, in press; Linehan, Goldfried, & Goldfried, Note 2), and test anxiety (Holroyd, 1976; Meichenbaum, 1972; Osarchuk, 1976) can be reduced by intervention procedures that focus on training individuals to modify their unrealistic belief systems.

Like much of the early behavior therapy research in general, therapeutic attempts at the reduction of test anxiety have focused

The research described in this article was supported in part by Grant MH24327 from the National Institute of Mental Health.

The authors are grateful to Ed Harpin for his assistance in carrying out the study, to Tom Holman for his suggestions regarding the statistical analyses, and to Gerald C. Davison and Sharon Foster for their comments on an earlier version of this article. The second author is now at the University of Washington, Seattle, Washington.

primarily on the use of systematic desensitization (Wine, 1971). The relevance of a more cognitively oriented approach in the treatment of test anxiety is noted by Wine (1971), whose review suggests that anxious individuals not only experience emotional arousal but also engage in excessive worry about the adequacy of their performance. Based on the assumption that test anxiety may be comprised of both "emotionality" and "worry" components (Liebert & Morris, 1967; Morris & Liebert, 1969), Meichenbaum (1972) developed a treatment package involving cognitive restructuring and modified systematic desensitization. Test-anxious subjects were provided with relaxation training, engaged in discussions of potentially unrealistic beliefs associated with test taking, and were then given practice in coping with imagined test-related situations by means of relaxation and self-instructions to focus on only the test itself. Compared with traditional systematic desensitization, this cognitive modification package produced greater reductions in test anxiety. Although Meichenbaum's study demonstrated that a treatment approach that includes the altering of cognitions can have an effect on reducing test anxiety, a more precise interpretation of these findings is limited by the inclusion of relaxation in the cognitive treatment package. Further, the exposure times for hierarchy presentation were longer for the cognitive modification subjects, since they were instructed to maintain the image while attempting to cope with their anxiety (Meichenbaum, Note 3).

The primary purpose of the present study was to determine whether a treatment procedure using only cognitive restructuring, incorporating the basic tenets of Ellis' therapeutic approach, could be successful in the reduction of test anxiety. The therapeutic procedure used was originally outlined by Goldfried et al. (1974), whose guidelines for the implementation of *systematic rational restructuring* are presented within a social learning framework. The treatment procedure, which is described in greater detail elsewhere (Goldfried & Davison, 1976), essentially involves the use of imaginatively presented hierarchy items to provide individuals with prac-

tice in ferreting out unrealistic concerns and worries, affording them the opportunity to place each situation into a more realistic perspective, and then using their newly acquired skills to reduce anxiety in real-life situations. In the present study, this treatment procedure was compared with an exposure-alone condition, in which the hierarchy items were presented without any instructions or directions for coping cognitively. The prolonged exposure group was included to control for possible extinction effects.

A second purpose of this study was to demonstrate the feasibility of conducting collaborative clinical outcome research with investigators at more than one setting. In an overview of the current status and future direction of psychotherapy research, Bergin and Strupp (1970) discussed the need for such coordinated or collaborative research efforts. As noted by them, a major difficulty associated with collaborative research in psychotherapy has been a general lack of standardization. By focusing on a specific target problem—test anxiety—and using comparable therapeutic techniques and assessment procedures, we wished to demonstrate that such standardization problems could be overcome.

Method

Participants

Participants were 15 men and 21 women who responded to advertisements for treatment of test anxiety at the State University of New York at Stony Brook and The Catholic University of America. They ranged in age from 18 to 49 years and were not being seen in therapy elsewhere. Of the 42 subjects who originally began the study, 6 were eliminated for failure to complete the treatment. The attrition was distributed among the three conditions as follows: 2 in rational restructuring, 1 in prolonged exposure, and 3 in waiting list control.

Procedure

After responding to local advertisements, interested individuals were sent a questionnaire battery, a program description, and a consent form. Persons who returned the consent form and questionnaire battery and who were available at scheduled therapy times were assigned by a within-sample matching technique (see Goldstein, Heller, & Sechrest,

1966) to systematic rational restructuring ($n=12$), prolonged exposure ($n=13$), or waiting list ($n=11$) conditions. Participants were then seen in person and were given a pretreatment analogue examination and an associated assessment battery. Therapy, administered in groups over six 1-hour sessions, was standardized across the two treatment conditions. Participants were reassessed within the week following the termination of therapy and at a 6-week follow-up.

The study was carried out in two waves. Approximately half of the individuals were seen at Stony Brook, and half participated 1 year later at Catholic University. Detailed therapy manuals, transcripts of therapy sessions, audiotapes of pilot sessions, and phone calls were exchanged to ensure maximum comparability between the two locations. All other aspects of the study were identical.

Measures

Two classes of measures were used in evaluating the results of the treatment procedures: a questionnaire battery and subjective reports of anxiety preceding an analogue examination situation. The questionnaire battery consisted of several scales designed to measure test anxiety: the S-R Inventory of Anxiousness (Endler, Hunt, & Rosenstein, 1962) for situations "taking an important exam" and "taking a weekly quiz"; the Suinn Test Anxiety Behavior Scale (Suinn, 1969); the Achievement Anxiety Test derived by Alpert and Haber (1960), which assesses facilitating as well as debilitating anxiety in examination situations; and the Test Anxiety Questionnaire (Mandler & Sarason, 1952), using Liebert and Morris' (1967) Worry and Emotionality subscores. Measures included to assess generalization of therapy effects to areas other than test anxiety were the S-R Inventory of Anxiousness for the situations "giving a speech," "going to a party," and "interviewing for a job"; the Fear of Negative Evaluation and Social Avoidance and Distress scales (Watson & Friend, 1969); and the Trait scale of the State-Trait Anxiety Inventory (Spielberger, Gorsuch, & Lushene, 1970). Participants also responded to a question measuring their expectations for benefit from therapy, using a 5-point scale ranging from "0% chance of success" to "100% chance of success."

After completing the questionnaire, participants were asked to take part in an actual "examination" situation. The examination was administered in small groups and consisted of the Wonderlic Personnel Test (Wonderlic, 1959) and the Digits Forward, Digits Backward, and Digit Symbol tests taken from the Weschler Adult Intelligence Scale. Participants were told that the test they were taking was selected from standardized IQ tests and that the results would be posted beside their names. Immediately following these instructions and before taking the exam, participants were administered the State scale of the State-Trait Anxiety Inventory (Spiel-

berger et al., 1970); the Anxiety Differential (Hush & Alexander, 1963); and the Experiences Questionnaire, which consists of Taylor Manifest Anxiety Scale items analyzed into Worry and Emotionality subscores (Morris & Liebert, 1969). Posttesting included the identical questionnaire battery and pre-exam measures, and the examination situation was composed of alternate forms of the tests administered during the pretest. At a 6-week follow-up, participants in the two treatment conditions were sent the same questionnaire battery plus forms for evaluating the program and their respective therapists. Because of ethical considerations, individuals in the waiting list control were offered therapy immediately following the posttest and were therefore not included in the follow-up assessment.

Therapy

Therapy sessions in the systematic rational restructuring and prolonged exposure conditions were conducted in groups that met weekly for six 1-hour sessions. Participants who missed sessions listened to audiotapes of the missed session, carried out the procedure described on the tape, completed in-session practice sheets, and returned these with homework assignments to an assistant. As a means of assessing the credibility of each treatment rationale, participants were asked to estimate the amount of success that they expected from therapy at the conclusion of the first session.

Systematic rational restructuring condition. The therapy program followed the systematic rational restructuring procedure outlined in Goldfried and Davison (1976). During the first session, the treatment rationale and therapy procedures were outlined, and participants received practice in imagining situations. During Sessions 2-6, the participants were presented with a standard 15-item hierarchy constructed on the basis of Stony Brook participants' pretest responses to the Suinn Test Anxiety Behavior Scale (Suinn, 1969). Three situations were presented in each session, and participants were instructed to imagine themselves in the situation throughout the presentation of each item and to attempt to reduce their anxiety by means of rational restructuring. Each item was presented for a total of four 1-minute trials. Immediately following each trial participants were instructed to record their self-defeating thoughts (e.g., "I'm going to fail this test, and then everyone's going to think I'm stupid"), their rational reevaluation (e.g., "Chances are I probably won't fail. And even if I do, people probably won't think I'm stupid. And even if they do, that doesn't mean that I am stupid"), and their anxiety levels before and after reevaluating. A brief group discussion followed the fourth presentation of each item. Participants were instructed to practice their reevaluation skills in vivo and were provided with homework sheets that served as the basis for discussion at the outset of the following session.

Prolonged exposure condition. A social-learning-based rationale was presented to subjects in this condition, emphasizing the importance of habituation and extinction in the reduction of anxiety. The first session of the treatment was identical in general format to that in the systematic rational restructuring condition. The same hierarchy presentation used for the restructuring condition was used; during scene presentations in this condition, however, participants were instructed to focus on their emotional reactions. In-session record forms were provided for the recording of feelings noted at the beginning and end of each imaginal presentation, and a group discussion was held after all four presentations of each item. Homework assignments, discussed at the beginning of each session, consisted of attending to their anxiety reactions in everyday situations.

Waiting list control. Participants in this condition were informed that because of the limited therapeutic time available, there would be a brief delay before they could be seen in treatment. Participants received the same pretest and posttest assessment battery as was administered to individuals in the two therapeutic contact conditions, and they were then offered therapy following the posttesting.

Therapists

The first and second authors served as therapists at their respective universities. A detailed therapy manual was used, hierarchy scenes were written out fully and were delivered verbatim, and transcripts and tapes of pilot sessions were exchanged to minimize any differences between the therapists. Both in-person meetings and frequent phone consultations during the progress of the experimental sessions insured that therapy and subject problems were handled in the same way by both therapists, and that the assessment procedures were administered in a comparable fashion. Each therapist had contact with approximately the same number of participants in each treatment condition.

Results

Separate univariate analyses of variance conducted on each dependent variable indicated no significant pretest differences among the three groups on any of the measures used in the study. Inasmuch as comparisons between therapists failed to reveal any main effect differences, the data from the two universities were combined in all subsequent analyses.¹

Pre-Post Treatment Effects

Questionnaire battery. The results of one-way analyses of covariance on each of the

questionnaire variables are presented in Table 1. On variables designed to measure test anxiety, there were significant treatment effects on the S-R Inventory of Anxiousness for both the "exam" and "quiz" situations, the Suinn Test Anxiety Behavior Scale, and the Achievement Anxiety Test Debilitating Anxiety scale. Newman-Keuls tests for differences between adjusted means revealed that participants in the systematic rational restructuring condition reported significantly less anxiety in exam situations, less anxiety on the Suinn scale, and less debilitating anxiety than did participants in the prolonged exposure condition. Both groups reported less anxiety on these three measures than did individuals in the waiting list control. Participants in the two therapy conditions did not differ from each other on S-R inventory reports of anxiety in quiz situations, but both reported significantly less quiz anxiety than did those on the waiting list. There were no significant differences among groups on the Facilitating Anxiety scale or on the Worry or Emotionality subscales of the Test Anxiety Questionnaire.

Significant generalization effects were found on the S-R Inventory of Anxiousness for "party" and "job interview" situations and on the Fear of Negative Evaluation and the Social Avoidance and Distress scales. Newman-Keuls comparisons of adjusted means indicated that participants in systematic rational restructuring reported less Fear of Negative Evaluation and Social Avoidance and Distress than those in either the prolonged exposure or the waiting list control conditions, which did not differ significantly from each other. On the S-R Inventory of Anxiousness for both party and job interview situations, participants in the systematic rational restructuring condition reported less anxiety than those on the waiting list; no difference was found between the restructuring and prolonged exposure groups. There were no significant differences among groups on the Trait scale of the State-Trait Anxiety

¹ The means and standard deviations for pretest, posttest, and follow-up assessments are available from the first author.

Table 1

One-Way Analyses of Covariance and Adjusted Means at Posttesting

Measure	<i>F</i>	Adjusted treatment <i>M</i>		
		Systematic rational restructuring	Prolonged exposure	Waiting list
Questionnaire Battery: Test Anxiety				
S-R inventory: exam	10.10***	35.67 _a	41.38 _b	46.55 _c

Preexamination anxiety				
State Anxiety scale of the STAI	2.72	35.46 _a	39.98 _a	42.43 _a
Anxiety Differential	<1	62.23 _a	62.41 _a	63.36 _a
Experiences Questionnaire: worry	4.62*	7.52 _a	9.08 _{a,b}	11.33 _b
Experiences Questionnaire: emotionality	3.08	6.91 _a	8.72 _a	11.79 _a

Note. Means in the same row with different subscripts differ from each other at least at the .05 level. For analyses of covariance, $df = 2, 32$. STAI = State-Trait Anxiety Inventory.

* $p < .05$.

** $p < .01$.

*** $p < .001$.

Inventory or the "speech" situation on the S-R inventory.

Focusing specifically on the direction of change, analyses of pre-post within-group differences by t tests (see Table 2) indicated a significant improvement in systematic rational restructuring across all but one measure designed to measure test anxiety (the Achievement Anxiety Test Facilitating scale) and on all but one measure of treatment generalization (the Trait scale of the State-Trait Anxiety Inventory). In contrast, the prolonged exposure participants improved significantly on only three variables; the Achievement Anxiety Debilitating scale, the Worry subscale of the Text Anxiety Questionnaire, and the Social Avoidance and Distress Scale. No pre-post differences were found on any measure for the waiting list control. Although

these within-group changes cannot be interpreted in terms of difference *between* the two treatment groups, they are nonetheless consistent with the overall superiority of the systematic rational restructuring group.

Examination situation. One-way analyses of covariance were carried out separately on posttest scores for the State scale of the State-Trait Anxiety Inventory, the Anxiety Differential, and the Worry and Emotionality subscales of the Experiences Questionnaire. As can be seen in Table 1, a significant main effect for treatment was found only on the Worry subscale. Newman-Keuls individual comparisons indicated that participants who received rational restructuring reported less preexam worry than those in the waiting list condition. No significant difference was found

between the systematic rational restructuring and the prolonged exposure conditions.

Analyses of pre-post differences, summarized in Table 2, indicated a significant reduction in subjective anxiety for the systematic rational restructuring condition on all but one variable, the Anxiety Differential. There was no significant pre-post improvement on any of the four measures for either the prolonged exposure or waiting list control.

Follow-up Evaluation

Analyses of covariance were carried out to test whether treatment differences were maintained on the questionnaire battery measures at follow-up 6 weeks after the termination of therapy. Results indicated that systematic rational restructuring participants reported significantly less anxiety than prolonged ex-

posure participants on the Suinn Test Anxiety Behavior Scale, $F(1, 22) = 8.25, p < .01$; the S-R Inventory of Anxiousness party situation, $F(1, 22) = 5.09, p < .05$; and the Social Avoidance and Distress Scale, $F(1, 22) = 5.71, p < .05$. In addition, there was a trend at the .10 level indicating less debilitating anxiety on the Achievement Anxiety Test in the systematic rational restructuring group as compared to the prolonged exposure group. There were no other significant differences between the two groups.

At the follow-up assessment, participants were asked to rate the therapy that they had received on several dimensions. Analyses by t tests indicated that participants in the systematic rational restructuring condition, compared to those in the prolonged exposure condition, were generally more satisfied with changes in themselves, $t(22) = 2.68, p < .05$.

The groups did not differ in their ratings of the helpfulness of therapy for test anxiety or on their estimate of the generalization effects of the therapies.

Expectancies and Liking of Therapist

During the pretest, participants were asked to rate their expectations for becoming less anxious in test-taking situations. This initial expectancy rating was used as one of the variables for the within-sample matching procedure. A check on this matching procedure was conducted by a one-way analysis of variance, which failed to reveal any significant differences among the three conditions. To check whether the two therapy rationales were equally credible, participants again rated their expectancy for success on the same 5-point scale after the first session. The absence of a significant *t*-test difference suggests that the two groups were comparable with regard to the nonspecific effects associated with expectancy of improvement and treatment demand characteristics.

At follow-up, participants in the two contact conditions were asked to rate their therapist on the following 5-point bipolar scales: incompetent-competent, unlikable-likable, not understanding-understanding, aloof-warm, and uncomfortable-comfortable. The ratings from the two conditions were all toward the positive pole and were not significantly different from each other on any of the scales. These findings suggest that differences between the two treatments cannot be attributed to nonspecific therapist differences while conducting the two treatments.

Discussion

The results of this study revealed a consistent pattern: Based on questionnaire measures of test anxiety, participants in the systematic rational restructuring condition experienced greater anxiety reduction, followed by those having undergone prolonged exposure to the same hierarchy items, whereas the waiting list control did not change. Only participants in systematic rational restructuring reported a significant pre-post decrease in subjective anxiety before an analogue test-taking situation. In addition to the reduction of test anxiety, participants in the restructur-

ing condition also reported greater generalization of anxiety reduction in social-evaluative situations.

Although the systematic rational restructuring procedure was found to be the most effective of three conditions, exposure alone also produced significant anxiety reduction. These findings corroborate the results of several other studies that have demonstrated that hierarchy exposure alone, particularly if it is prolonged or repeated, can be an effective therapeutic procedure for anxiety reduction (e.g., D'Zurilla, Wilson, & Nelson, 1973; Goldfried & Goldfried, 1977; Malleon, 1959). These therapy-analogue findings are consistent with the animal literature on extinction of avoidance via exposure and response prevention (Wilson & Davison, 1971). As indicated in the present study, however, active attempts to cope with one's anxiety by means of cognitive reappraisal adds to any anxiety reduction associated with extinction or habituation and greatly facilitates generalization to nontreated targets.

This study has also demonstrated that collaborative research with investigators at different settings is possible and that it can be a useful approach to increasing the number of participants available in clinical outcome research and facilitating the generalizability of the findings. Such collaborative research efforts are feasible provided that close coordination and appropriate methodological precautions are taken, such as insuring the standardization of treatment procedures, comparability of participants, and equivalence of outcome measures.

Although Meichenbaum's (1972) cognitive modification procedure for reducing of test anxiety consisted of a treatment package containing rational-emotive therapy, self-instructions, and relaxation components, our results reveal that cognitive restructuring alone is effective. It should be noted, however, that the cognitive restructuring procedure used by Meichenbaum is somewhat different from the intervention procedure used in the present study. Although Meichenbaum included a rational-emotive therapy component, the self-instructions used during hierarchy presentation involved self-statements to encourage participants to pay attention to

the task at hand. By contrast, participants in rational restructuring were taught to tune in to any of their unrealistic concerns and worries and to put them into a more realistic perspective. Thus, the results of the present study add to the increasing number of outcome studies indicating that the cognitive reappraisal of anxiety-provoking situations is a markedly effective treatment procedure for the reduction of anxiety.

Psychological Androgyny and Interpersonal Behavior

Jerry S. Wiggins and Ana Holzmuller
University of British Columbia, Vancouver, Canada

Bem's measure of psychological androgyny was derived from only two relatively desirable dimensions of interpersonal behavior that may, or may not, implicate other less desirable traits that are sex role stereotyped. From an item pool of 1,710 trait-descriptive adjectives, sets of masculinity and femininity scales were assembled that were comparable to "traditional" scales and to those developed by Bem and by Heilbrun. The pool also contained items from eight scales that form an interpersonal circumplex. One hundred eighty-seven college men and women who rated themselves on the 1,710 adjectives were classified as stereotyped, near-stereotyped, or androgynous by Bem's criteria. Bem's measure of psychological androgyny appears to reflect a highly generalizable personological construct that implicates both desirable and undesirable dimensions of interpersonal behavior. Heilbrun's scales are both empirically and conceptually similar to Bem's, and both scale sets differ from traditional masculinity-femininity measures. There is a possibility that androgynous men are more flexible in their interpersonal behavior than androgynous women.

Until very recently, the psychological construct of "masculinity-femininity" has been characterized by a conceptual fuzziness that has permitted unrelated and even contradictory attributes of persons to be viewed as indicants of a monolithic process. Constantine's (1973) critical review of the major psychological tests of masculinity-femininity, developed during the last 40 years, cleared the air for new approaches to an old problem. Bem's (1974) work on the construct of psychological androgyny is one such new approach. Her formulations place a unique emphasis on certain classes of *interpersonal behavior* that are generally considered more

desirable or appropriate for one sex than the other.

Bem (1974) asked male and female judges to rate the desirability of traits for men and women separately. Traits that were rated by both sexes as more desirable for men than for women were called *masculine*, and traits that were rated by both sexes as more desirable for women than for men were called *feminine*. Traits that were rated by both sexes as equally desirable for men and women were called *neutral*. Scales were developed from these item pools and combined to yield a measure of "psychological androgyny." Specifically, the algebraic difference between femininity and masculinity scales was taken to be an index of androgyny. Individuals scoring high on this index are feminine stereotypes, individuals with negative scores are masculine stereotypes, and individuals with scores near zero are androgynous. In a series of studies, Bem (1975; Bem & Lenney, 1976; Bem, Martyna, & Watson, 1976) has marshaled evidence that androgynous persons are flexible in their social behavior and that they can vary their behavior according to situational demands, rather than according to sex role stereotypes.

This research was supported by Canada Council Research Grant S75-0109. We are grateful to Lewis R. Goldberg for making available the large data bank on which our analyses were conducted. Computer programming assistance was graciously provided by Frank Flynn. We would also like to acknowledge the help in data processing provided by Doreen Ridgeway, Barbara J. Marston, and Cecilie Lacey.

Requests for reprints should be sent to Jerry S. Wiggins, Department of Psychology, University of British Columbia, Vancouver, British Columbia, Canada V6T 1W5.

Other than restricting her inquiry to desirable interpersonal traits, Bem did not specify the manner in which the universe of content of interpersonal behavior was defined. There is now considerable precedent for defining the universe of content of interpersonal behavior with reference to a two-dimensional circumplex of variables of the kind illustrated in Figure 1 (e.g., Becker & Krug, 1964; Benjamin, 1974; Carson, 1969; Foa & Foa, 1974; Leary, 1957; Lorr & McNair, 1963; Rinn, 1965; Schaefer, 1959; Stern, 1970; Swensen, 1973). The system represented in Figure 1 was developed as part of a larger project whose eventual aim is a comprehensive taxonomy of trait-descriptive terms (Wiggins, Note 1). Like the Leary (1957) system of interpersonal behavior on which it is based, the eight variables illustrated in Figure 1 can be decomposed into 16 more narrowly defined variables. In principle, the number of different variables is limited only by the reliability with which respondents can distinguish between closely synonymous words and phrases.

Inspection of the items comprising Bem's Masculinity scale revealed that virtually all of the classifiable items fell within the dominant-ambitious vector of our interpersonal model (e.g., assertive, ambitious, dominant, forceful). Similarly, most of the classifiable

items in Bem's Femininity scale fell within the warm-agreeable vector of the same circumplex (e.g., affectionate, compassionate, sympathetic, tender). Lippa (1977) reported the results of an item analysis of the Bem Sex-Role Inventory (BSRI) in which the items *dominant* and *assertive* were the best markers of the Masculinity scale and the items *compassionate* and *tender* were the best markers of the Femininity scale. Bem (in press) is well aware of the interpersonal content of her scales and uses the terms *instrumental* and *agentic* to describe the Masculinity scale and the terms *expressive* and *communal* to describe the Femininity scale.

Since the two vectors at issue are known to be orthogonal, it is clear why Bem discovered a nonbipolar dimension of masculinity-femininity. But it is also clear that Bem's definition of psychological androgyny is based on only two of the eight major dimensions of interpersonal behavior and that it ignores possible sex role stereotypes related to *undesirable* interpersonal behavior. It could also be the case that the flexibility associated with Bem's definition of psychological androgyny is a more general personality characteristic that subsumes sex role stereotypes. According to the logic of the original Leary (1957) system, the self-actualized individual is one

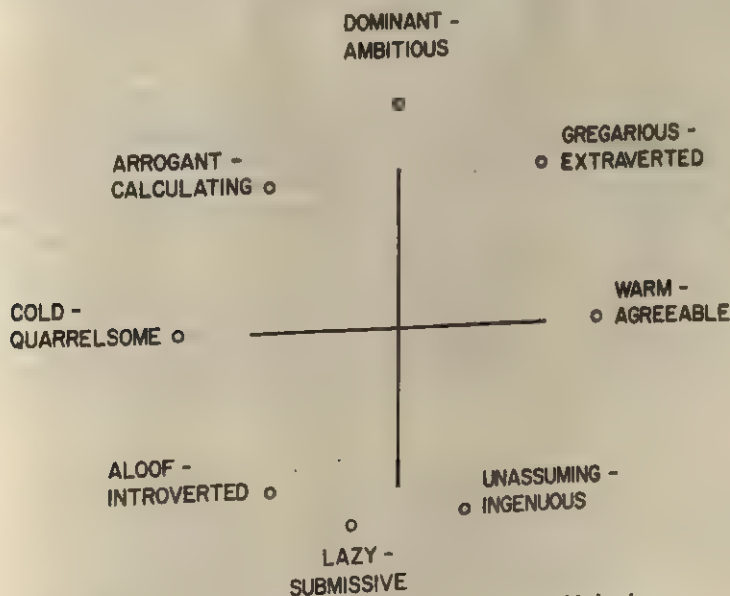

Figure 1. Eight-variable representation of interpersonal behavior.

who is capable of responding in all interpersonal dimensions as the situation demands. Hence, the actualized person is one who has a relatively flat profile of interpersonal traits. Such an individual would, by definition, be androgynous. However, an androgynous person would not necessarily be actualized by Leary's definition.

In the research to be reported here, the self-presentations of masculine-stereotyped, feminine-stereotyped, and androgynous persons are examined with reference to a much broader universe of personological content than has previously been used. Although particular attention was paid to the interpersonal dimensions illustrated in Figure 1, the universe of content sampled was rigorously representative of the entire domain of what Allport and Odbert (1936) called *stable biophysical traits*. In addition, the relationship between bipolar and orthogonal definitions of sex differences was examined in the medium of self-report.

Method

Subjects

The data used in the present analyses were provided by Lewis R. Goldberg. A group of 204 students in an introductory personality class at the University of Oregon rated the self-applicability of 1,710 trait-descriptive adjectives on a 9-place Likert scale ranging from "extremely inaccurate" to "extremely accurate." The students received course credit for this exercise, and they were promised feedback at a later date. The adjectives were partitioned into 10 blocks, and the order in which these blocks were administered was counterbalanced across the sample. The students were allowed to complete the test forms at their own pace over a period of weeks under specific instructions to stop when fatigued or bored. The resultant protocols were checked for carelessness, as indicated by semantic inconsistency, and 17 subjects were eliminated on this basis. The total number of complete usable records was thus 187 (117 females and 70 males).

Item Pool

The pool of items used has historical roots in the work of Allport and Odbert (1936), who identified 4,504 terms in Webster's (1925) *New International Dictionary* that were considered genuine personality traits. Norman (Note 2) expanded this list by consulting Webster's *Third New International Dictionary*,

Unabridged, and, by a variety of procedures, reduced the new list to 2,800 terms. This revised list was, in turn, reduced by Goldberg and Norman to the 1,710 adjectives used in the present study. This list of 1,710 adjectives (Goldberg, Note 3) is thus broadly representative of terms in the English language that describe stable personality traits.

Sex Role Inventory

Forty-three of the 60 items in the BSRI appear in the item pool just described. The majority of items that do not appear are phrases rather than single items. Consequently, single adjectives were identified, in the 1,710 pool, that were closely synonymous with the BSRI phrases (e.g., "decisive" for "makes decisions easily"). Synonymous adjectives were easily found for all but two of the adjectives and phrases in the BSRI: "athletic" on the Masculinity scale and "loves children" on the Femininity scale. Thus, our revised single-adjective sex role inventory consisted of a 19-item Femininity scale, a 19-item Masculinity scale, and a 20-item Neutral scale.

Lacey (Note 4) administered both the original BSRI and our single-adjective sex role inventory to 110 young men and women from the Vancouver, Canada, area. The Femininity, Masculinity, and Neutral scales from the two inventories correlated .92, .97, and .96, respectively, in that sample. Comparable alpha coefficients were also obtained for the two sets of scales. Thus, the measure of psychological androgyny used in the present study is empirically equivalent to Bem's, although it is based on slightly different items.

Interpersonal Circumplex

Sixteen eight-item scales were used to measure the interpersonal dimensions named in Figure 1 (e.g., dominant, ambitious, arrogant, calculating). These 16 scales were scored as octants by combining adjacent variables (e.g., dominant-ambitious, arrogant-calculating). The eight-variable display in Figure 1 is an actual *empirical* plot of the loadings of these eight scales on two hand-rotated principal components extracted from the intercorrelations among the scales in the present sample of 187 subjects. Although these scales were mainly developed on the present sample (Wiggins, Note 1), the same clear circumplex structure has been found in samples of Australian and Canadian students as well (Wiggins & Marston, Note 5).

Masculinity-Femininity Scales

We constructed two relatively pure measures of self-reported "gender," as opposed to sex-related traits, by clustering items that almost necessarily would be answered differently by men and women. A five-item Woman scale (feminine, girlish, lady-

like, unfeminine, womanly) had an alpha coefficient of .96 in the total sample. A five-item Man scale (manly, masculine, unmanly, unmasculine, virile) had an alpha coefficient of .93. The correlation between the two scales ($r = -.91$) approached their estimated reliabilities. Needless to say, these two scales, and the items that comprise them, have non-overlapping distributional properties in male and female samples. The scales are, in effect, caricatures of "traditional" masculinity-femininity scales based on items that empirically discriminate men from women.

Although in some respects, a traditional masculinity-femininity scale (Constantinople, 1973, p. 397), the Masculinity-Femininity scale of Gough and Heilbrun's (1965) Adjective Check List (ACL) attempts "to capitalize on both biological and psychological sex differences" (Heilbrun, 1976, p. 185). The items were selected on the basis of their ability to discriminate between college males identified with masculine fathers and college females identified with feminine mothers (Cosentino & Heilbrun, 1964). Inspection of the 28-item masculine subscale and the 26-item feminine subscale reveals that the scales have highly similar contents to Bem's Masculinity and Femininity scales. The items *masculine* and *feminine* are included in the two scales, as they are in Bem's, but in general the two scales are saturated with dominance and nurturance, respectively. Although originally scored as a single scale (masculine minus feminine), normative and psychometric information is now available for both subscales (Heilbrun, 1976). In the present pool of 1,710 adjectives, all but 2 adjectives ("handsome" and "strong") were available for the masculine subscale and all but one ("praising") for the feminine subscale. The self-applicability of the adjectives was evaluated using a 9-place scale rather than with the usual checklist format.

Experimental Design

In the sample of 187 subjects, we identified groups of stereotyped, near-stereotyped, and androgynous

men and women using Bem's (1974) *t*-ratio criteria.¹ Table 1 shows the percentage of subjects in each of the groups. The 11 "sex-reversed" subjects were not included in the present analysis. Within a 3×2 analysis of variance design, subjects were classified by group (stereotyped, near-stereotyped, androgynous) and by sex (men, women). Scores on the interpersonal adjective scales were entered separately as dependent variables. For each interpersonal variable, this permitted an evaluation of main effects for groups (stereotyped and androgynous groups irrespective of gender), for gender (sex differences in responding irrespective of groups), and for the interaction between these two factors.

Results and Discussion

Sex Roles and the Interpersonal Circumplex

As expected, a main effect for groups was not found for any of the eight interpersonal variables. Stereotyped, near-stereotyped, and androgynous groups did not differ in self-report on the interpersonal variables when the sexes were combined. However, as can be seen from Table 2, there were highly significant sex differences for all but one (aloof-introverted) of the interpersonal variables. Men scored higher on dominant-ambitious, arrogant-calculating, and cold-quarrelsome, whereas women scored higher on lazy-submissive, unassuming-ingenuous, warm-agreeable, and gregarious-extraverted. Sex differences in self-report are not restricted to the relatively desirable vectors of dominance and nurturance; they occur in almost all sectors of the interpersonal circumplex.

To what extent are the sex differences on these interpersonal variables related to the

Table 1
Percentage of Subjects in the Oregon Sample
Classified as Masculine, Feminine, or
Androgynous

Classification	Males ^a	Females ^b
Feminine ($t \geq 2.026$)	3	36
Near feminine ($1.01 < t < 2.026$)	9	28
Androgynous ($-1.01 \leq t \leq +1.01$)	47	33
Near masculine ($-2.026 < t < -1.01$)	30	1
Masculine ($t \leq -2.026$)	11	2

^a $n = 70$.

^b $n = 117$.

¹ This *t* ratio is based on the algebraic difference between femininity and masculinity scores for each subject. There are a number of shortcomings to such a measure (Strahan, 1975), not the least of which is its inability to distinguish androgynous subjects who score high on both masculinity and femininity from "androgynous" subjects who score low on both masculinity and femininity. As a consequence, Bem (1977) now recommends a fourfold classification based on median splits on masculinity and femininity. However, designs such as the present one that analyze interactions between sex role classification and other variables require the additional "near-stereotyped" groups yielded by the difference score method. Within this design, it is still possible to note differences between high-high and low-low androgynous subjects.

Table 2
Analyses of Variance of Interpersonal Variables

Variable	Sex (A)		Group (B)		A × B	
	F	p	F	p	F	p
Dominant-ambitious	21.3	.00001	.3	ns	30.6	.00000
Arrogant-calculating	24.6	.00000	.3	ns	3.4	.04
Cold-quarrelsome	45.4	.00000	.3	ns	2.3	ns
Aloof-introverted	2.3	ns	1.9	ns	7.5	.0008
Lazy-submissive	15.2	.0001	2.3	ns	14.6	.00000
Unassuming-ingenuous	39.1	.00000	1.3	ns	9.2	.0002
Warm-agreeable	33.2	.00000	1.3	ns	5.9	.003
Gregarious-extraverted	13.8	.0003	1.7	ns	2.6	ns

stereotyped, near-stereotyped, and androgynous classifications of the sex role inventory? From the final column of Table 2, it can be seen that significant interactions between gender and sex role classification occurred on six of the eight interpersonal variables. The pattern of these interactions is consistent with Bem's concept of androgyny for all but one (again, aloof-introverted) of the six interpersonal variables. The greatest difference in self-report occurred between male and female stereotypes, the next greatest between male and female near stereotypes, and the least difference between male and female androgynous subjects. Despite substantial overall sex differences on arrogant-calculating, lazy-submissive, unassuming-ingenuous, and warm-agreeable, there were no statistically reliable differences between androgynous men and women on these variables.² Although the difference between androgynous men and women on dominant-ambitious was statistically significant, it involved a "crossover" effect that is illustrated in Figure 2. Androgynous women presented themselves as significantly *more* dominant-ambitious than androgynous men. A similar crossover occurred on lazy-submissive, although the difference between androgynous men and women was not significant.

These results suggest that Bem's measure of androgyny reflects a highly generalizable personological construct. Persons classified as androgynous by the sex role inventory are nonstereotypic, not only in the realms of dominant-ambitious and warm-agreeable behavior but in the realms of arrogant-calculating, lazy-submissive, and unassuming-ingenu-

ous behaviors as well. Persons classified as sex role stereotyped by the Bem inventory are stereotyped on the same five dimensions of interpersonal behavior.

The data suggest that the undesirable dimension of cold-quarrelsome behavior is not the functional opposite of the desirable warm-agreeable dimension, with respect to sex role stereotypy. The trend of cold-quarrelsome is clearly for the largest sex differences to occur in the stereotyped groups and the smallest in the androgynous groups. However, the interaction of sex and group classification was not significant, and there was no trend toward a crossover effect as there was with warm-agreeable. In general, none of the subjects presented themselves as particularly cold and quarrelsome, although men were more willing to do so than women.

Striking exceptions to the foregoing trends occurred with reference to aloof-introverted and gregarious-extraverted, which represent poles of the ubiquitous "introversion-extraversion" dimension of personality research. On both variables the differences between androgynous men and women were significant, whereas those between stereotyped men and women were not. The results of the analysis of aloof-introverted are particularly anomalous. As can be seen from Figure 3, the two stereotyped groups are indistinguishable, as are the two near-stereotyped groups. However, androgynous women presented them-

² All post hoc comparisons between sex role groups were evaluated by the Newman-Keuls procedure with alpha set at $p \leq .05$.

selves as significantly less introverted than androgynous men, and, in fact, significantly less introverted than all groups. Thus, there is a significant interaction between sex and group classification in the absence of significant main effects for the latter two factors. A similar trend emerged from the analysis of gregarious-extraverted, although no interaction or crossover trend was evident. All female groups reported more extraversion than their male counterparts, although the only significant difference occurred between androgynous women and men.

It is tempting to speculate on the reasons for the lack of generalizability of Bem's index of psychological androgyny to the domains of introverted and extraverted behaviors. It appears that introversion is not a sex stereotyped role, as evidenced by the lack of overall gender differences, although androgynous women clearly see themselves as less introverted than their male counterparts. Although there are significant gender differences in self-reported extraversion, the lack of an interaction with sex role classification raises the possibility that this relatively desirable variable is not sex stereotyped either. If one thinks of the gregarious-extraverted social role as a blend of dominance and nurturance, then it is understandable that both men and women could assume it without violating stereotypes.

Sex Roles and Trait-Descriptive Adjectives

To what extent do the sex role groups differ among themselves on variables other than those of the interpersonal domain? The 1,710 adjectives to which all subjects responded embrace a variety of personal characteristics other than the strictly interpersonal. Although a final taxonomy of this item pool has not yet been achieved, a preliminary set of distinctions has been made among the domains of *interpersonal traits* (dominant, warm), *temperamental traits* (animated, high-strung), *character traits* (moral, unprincipled), *material traits* (miserly, materialistic), *attitudes* (prejudiced, progressive), *mental predicates* (analytic, intelligent), and *social roles* (aristocratic, cliquish) (Wiggins, Note 1). Differ-

Figure 2. Mean scores of male and female sex role groups on dominant-ambitious.

ences in self-report between stereotyped, near-stereotyped, and androgynous groups were examined in all of these domains by comparing the group means on all 1,710 adjectives. Even with highly stringent significance levels, this procedure produced an *embarras de richesses* that is not easily summarized nor confidently interpreted. Nevertheless, several trends were apparent from these data that are worth noting, if only as guides for future investigations.

With remarkably few exceptions, the adjectives that differentiated sex role groups from each other were *interpersonal* in nature and could be easily classified within the 8-variable system used in the main analysis or

Figure 3. Mean scores of male and female sex role groups on aloof-introverted.

within the more refined 16-variable system. In virtually all cases, interpersonal adjectives that differentiated two sex role groups did so in a manner that was consistent with the findings of the analyses of variance reported earlier. In comparing androgynous with masculine males, the former presented themselves as warm and submissive and the latter as dominant and cold. In comparison with feminine females who described themselves as meek and submissive, androgynous females described themselves as dominant and extraverted. The comparisons of androgynous and stereotyped groups on the 1,710 adjectives mainly confirmed the earlier analyses with many more interpersonal adjectives.

The adjectives that differentiated androgynous men from androgynous women served to confirm the earlier analysis and to extend it somewhat into the domain of temperament. The 51 adjectives listed in Table 3 reliably distinguished ($p < .001$) the two groups. On the item *aggressive*, for example, the mean item response for androgynous females was 6.54 and the mean item response for androgynous males was 4.82. The item *antisocial* was answered as significantly more self-descriptive by androgynous males than by androgynous females. The starred items are significant under an ultraconservative criterion ($p = .05/1,710 = .000029$). In comparison with the androgynous male, the androgynous female presents herself as extraverted, warm, excitable, emotional, aggressive, and vivacious. In

contrast, the androgynous male is introverted, cold, calm, unemotional, passive, and undramatic. In this sample of subjects, at least, males and females achieved psychological androgyny by different routes. Although both androgynous groups clearly differed from stereotyped groups of the same gender, they also differed from each other in ways that both support and contradict sex role stereotypes.

The present data also permitted a test of the hypothesis that subjects who are classified as androgynous on the basis of high and equal scores on femininity and masculinity (high-high) differ from subjects who achieve that classification by low and equal scores (low-low), primarily with respect to *self-esteem* (Spence, Helmreich, & Stapp, 1975). Like Bem (1977), we were unable to find many examples of truly "low-low" androgynous subjects in our sample. Nevertheless, we were able to gain some information on this issue by contrasting the upper and lower 25% of each androgynous group. Table 4 displays the adjectives that differentiated high-high and low-low androgynous subjects under this definition.

From among the considerable number of adjectives that differentiated high-high from low-low androgynous females, we have reported only those that did so at the conservative significance level. Overall it is clear that the high-highs attributed positive characteristics to themselves, whereas the low-lows

^a $n = 10$.

^b $n = 8$.

attributed negative characteristics to themselves. More germane to the hypothesis, the high-highs described themselves on the rating scale as more *certain* ($M = 6.90$) than did the low-lows ($M = 3.90$). Similarly, the low-lows described themselves as more *self-doubting* (6.30 vs. 3.00) and as more *unassured* (5.10 vs. 2.00).

There were fewer adjectives that differentiated the male groups, and consequently a less stringent significance level ($p < .001$) was used to detect trends. As was true of the females, the high-high males attributed highly positive characteristics to themselves in contrast to the low-low males. The high-highs presented themselves as more *self-respecting* (8.00) than did the low-lows (5.75). The low-lows described themselves as more *aimless* (4.62) than did the high-highs (1.87). In general, the data for both men and women suggest that high-high androgynous subjects have considerably more self-esteem than do low-low subjects. This trend is especially interesting in the present sample in which high-highs and low-lows differed only slightly from each other in their masculinity and femininity scores.

The fact that high-high and low-low androgynous subjects differed in self-esteem could restrict the generalizability of the conclusions drawn concerning differences between

androgynous males and androgynous females (Table 3). Consequently, differences in self-report between androgynous males and androgynous females were reanalyzed excluding the lower 25% of both groups, a liberal definition of low-lows. None of the findings in Table 3 change when low-low androgynous subjects are excluded. Where differences between high-high and low-low groups occurred, they served only to accentuate the trends reported in Table 3.

Masculinity-Femininity Scales and Interpersonal Behavior

Three different sets of masculinity and femininity scales were scored in the present sample: (a) Bem's Masculinity and Femininity scales from the BSRI; (b) Heilbrun's Masculinity and Femininity scales from the ACL; and (c) the five-item Man and Woman scales that were constructed as markers of traditional masculinity-femininity scales. The intercorrelations among these scales, and their reliabilities, are presented in Table 5. The BSRI and ACL scales are of comparable homogeneity, and the Man and Woman scales are, as expected, highly homogeneous despite the small number of items involved.

The correlations between comparable BSRI and ACL scales suggest that the two sets of

Table 5

Intercorrelations Among Femininity, Masculinity, and Femininity Minus Masculinity Scores

Variable	1	2	3	4	5	6	7	8
1. BSRI-F	(.718)							
2. BSRI-M	-.127	(.830)						
3. BSRI-D	.678	-.816						
4. ACL-F	.731	-.121	.516	(.771)				
5. ACL-M	-.257	.873	-.800	-.217	(.831)			
6. ACL-D	.599	-.686	.857	.724	-.830			
7. Woman	.641	-.354	.636	.627	-.409	.647	(.963)	
8. Man	-.562	.382	-.611	-.578	.423	-.629	-.913	(.932)
9. WM-D	.616	-.376	.638	.617	-.425	.652	.980	-.976

Note. BSRI-F = Bem Sex-Role Inventory Femininity scale; BSRI-M = Bem Sex-Role Inventory Masculinity scale; BSRI-D = difference between the two scales; ACL-F = Adjective Check List Femininity scale; ACL-M = Adjective Check List Masculinity scale; ACL-D = difference between the two scales; WM-D = difference between the Woman and Man scales. For $N = 187$, an r of .187 is significant at the .01 level. The reliabilities (Cronbach's alpha) of the masculinity and femininity scales appear in parentheses. The correlation coefficients in italics indicate the degree of bipolarity that exists between masculinity and femininity scales in the three sets.

measures are closely related. The masculinity measures are correlated .873, the femininity measures are correlated .731, and the difference measures (femininity minus masculinity) are correlated .857. Both the BSRI and the ACL scale sets are substantially correlated with the traditional masculinity-femininity scales. The ACL Masculinity scale was more highly correlated with the Man scale than was the BSRI Masculinity scale, but the BSRI Femininity scale was more highly correlated with the Woman scale than was the ACL Femininity scale. The BSRI difference score (femininity-masculinity) was correlated .628 with woman minus man, and the ACL difference score was correlated .564 with the same index. Although the BSRI and the ACL scale sets are conceptually distinct from the traditional masculinity-femininity measures, they share a considerable amount of variance in common. The extent of these relationships may be exaggerated by the use of a common method of measurement (9-place Likert scales) in the present study, but it is expected that the scales would also be highly correlated in their original formats.

The traditional Man and Woman scales are strongly bipolar ($-.913$), the ACL scales are only slightly related ($-.217$), and the BSRI scales are the most independent ($-.127$). The BSRI and ACL scales also differ from the traditional scales in the extent to which mascu-

linity and femininity determine the difference score (femininity minus masculinity). For the traditional scales, the correlation between man and woman minus man ($-.976$) was almost identical to the correlation between woman and woman minus man (.980). For the BSRI scales, however, the correlation between masculinity and the difference score ($-.816$) was higher than the correlation between femininity and the difference score (.678). The same is true for the ACL scales. This suggests that in the present sample at least the greatest contribution to variance on the androgyny index comes from the Masculinity scale.

The conceptual similarity of the ACL scales to the BSRI scales is most evident from the pattern of correlations of these two scale sets with the interpersonal variables used in the present study. From Table 6 it can be seen that the masculinity and femininity scales from the BSRI and ACL behave as variables that are closely related to the circumplex positions of dominant-ambitious and warm-agreeable, respectively. The masculinity scales have their highest positive correlations with dominant-ambitious and their highest negative correlations with the opposite vector of lazy-submissive. The femininity scales have their highest positive correlations with warm-agreeable and their highest negative correlations with the opposite vector of cold-quarrelsome. This orthogonal pattern is also clearly evi-

dent in the correlation of the androgyny indices (feminine minus masculine) with the interpersonal variables. From Table 6 it can be seen that the ACL androgyny index has its two highest positive correlations with lazy-submissive and warm-agreeable and its two highest negative correlations with dominant-ambitious and cold-quarrelsome. The same pattern is evident for the BSRI androgyny index, with the slight exception that the negative correlation with arrogant-calculating exceeds the negative correlation with cold-quarrelsome. Aside from this slight exception, the patterns of correlations of the BSRI and ACL scale sets with the interpersonal circumplex variables are virtually identical.

The pattern of correlations of the traditional Man and Woman scales with the interpersonal variables is quite different. The Man, Woman, and Woman minus Man scales all have their highest correlations with the single bipolar dimension of cold-quarrelsome versus warm-agreeable. Masculinity is associated with hostility and femininity with warmth. The apparent association between masculinity and hostility is especially interesting, since none of the items in the Man or Woman scales implicate interpersonal variables.

Psychological Androgyny or Interpersonal Flexibility?

According to Bem, the androgynous person is both dominant and nurturant and thus can vary his or her behavior to meet situational demands. Stereotyped males would, presumably, emphasize dominance and suppress nurturance, and stereotyped females would emphasize nurturance and suppress dominance. Earlier in this article we raised the possibility that the flexibility of androgynous persons may be part of a broader pattern of flexibility that is expressed in all or most dimensions of interpersonal behavior. By this reasoning, the androgynous person's profile of interpersonal variables would be relatively flat, and the stereotyped person's profile would be both positively and negatively spiked on variables that are highly sex stereotyped.

The profile variability of sex role groups

Table 6
Correlations Between Masculinity-Femininity Scale Sets and Interpersonal Variables

Scale	Dominant-ambitious	Arrogant-calculating	Cold-quarrelsome	Alloof-introverted	Lazy-submissive	Unassuming-ingenuous	Warm-agreeable	Gregarious-extraverted
BSRI-F	-.050	-.266	-.609	-.175	.168	.283	.750	.388
BSRI-M	.797	.512	.204	-.251	-.600	-.291	-.073	.374
BSRI-D	-.620	-.534	-.506	.084	.540	.381	.492	-.051
ACL-F	-.072	-.124	-.521	-.281	.206	.141	.731	.478
ACL-M	.763	.678	.376	-.126	-.566	-.413	-.219	.241
ACL-D	-.580	-.550	-.563	-.071	.517	.372	.572	.103
Woman	-.134	-.316	-.453	-.148	.186	.219	.436	.257
Man	.173	.316	.431	-.178	-.186	-.188	-.379	-.240
WM-D	-.156	-.323	-.452	-.166	.190	.208	.418	.255

Note. BSRI-F = Bem Sex-Role Inventory Femininity scale; BSRI-M = Bem Sex-Role Inventory Masculinity scale; BSRI-D = difference between the two scales; ACL-F = Adjective Check List Femininity scale; ACL-M = Adjective Check List Masculinity scale; ACL-D = difference between the two scales; WM-D = difference between the Woman and Man scales. For $N = 187$, an r of .187 is significant at the .01 level.

was examined with reference to scores on the full set of 16 interpersonal variables. Sixteen variables were used to ensure an adequate number of observations for profile analysis. Means and standard deviations were computed separately in the total group of men and in the total group of women for each of the 16 variables. All subjects' raw scores were then converted to standard scores based on either male or female norms. Mean standard scores were computed for male and female stereotyped, near-stereotyped, and androgynous groups. This resulted in a mean profile of 16 interpersonal variables, for each sex role group, that had been standardized with reference to the total same-sex sample. The variance of a group's profile of mean standard scores was used as an index of profile variability for that group. Differences in profile variability between sex role groups were assessed by a variance ratio (F) with 15, 15 degrees of freedom.

The hypothesis that androgynous persons would have relatively flat profiles of interpersonal variables received considerable support for male subjects. Androgynous males had a flat profile of scores that were close to the means for the total group. In contrast, the profile of scale scores for stereotyped males was much more variable, with a high spike on dominant and low spikes on warm and submissive. The interpersonal profile of stereotyped males was significantly ($p < .001$) more variable than those of near-stereotyped males and androgynous males. The profile of near-stereotyped males was slightly ($p < .02$) more variable than that of androgynous males.

The hypothesis that androgynous persons would have relatively flat profiles of interpersonal variables was strikingly disconfirmed for female subjects. The index of profile variability was highest for androgynous females and next highest for stereotyped females; the slight difference between the two groups was not statistically significant. Near-stereotyped females were least variable, and their relatively flat profile was significantly ($p < .001$) less variable than those of androgynous and stereotyped females.

Stereotyped females had a profile that was

high on introverted, submissive, and unassuming, and was low on dominant, extraverted, and arrogant. The profile of androgynous females was a *mirror image* of this pattern. The correlation between the profile of stereotyped females and that of androgynous females was $-.96$ ($p < .001$). Rather than differing from stereotyped females in profile variability, androgynous females were equally variable, but in ways that run counter to sex role stereotypes. Androgynous males differ from stereotyped males in both the mean level and variability of their profile of interpersonal variables. In contrast, androgynous females are, interpersonally, the *opposite* of their stereotyped counterparts. The profile of androgynous females was significantly ($p < .001$) more variable than that of androgynous males, and it is again clear that androgyny does not reflect a uniform set of dispositions in men and women. To the extent that a flat profile of variables is an index of interpersonal flexibility, androgynous women would be characterized as "inflexibly androgynous," whereas androgynous men would be characterized as "flexibly androgynous."

To investigate the possibility that the observed patterns of profile variability may have been affected by the presence of low-low androgynous subjects, the data were analyzed with the lower 25% of both androgynous groups excluded. This had the effect of making the profile of androgynous males slightly less variable and the profile of androgynous females slightly more variable. All of the major trends previously noted remained the same.

Conclusions

Despite the fact that it was derived from only two relatively desirable dimensions of interpersonal behavior, Bem's measure of psychological androgyny appears to reflect a highly generalizable personological construct. Persons classified as androgynous or as stereotyped by the BSRI will tend to be androgynous or stereotyped on five of the eight major dimensions of interpersonal behavior. Although there was a trend for this to be true of the highly undesirable cold-quarrelsome

dimension, it was not a significant one. A genuine exception to the generalizability of BSRI sex role classifications occurred with respect to the dimensions of introversion and extraversion. Women were more extraverted than men in all sex role groups, with the greatest differences occurring between androgynous groups. Although stereotyped groups did not differ on introversion, androgynous women were clearly less introverted than androgynous men. The possibility that the dimensions of introversion and extraversion are not sex role stereotyped is worth investigating in other samples of subjects.

Sex role groups defined by the BSRI differed from each other in self-report primarily on *interpersonal adjectives* as opposed to adjectives denoting temperamental, characterological, material, attitudinal, or intellectual characteristics. Androgynous groups differed from stereotyped groups of the same gender, but they also differed from each other in ways that both support and contradict sex role stereotypes. Androgynous men and women who scored high on both masculinity and femininity scales differed from their same-gender androgynous counterparts who scored low on both scales. The high-high androgynous subjects characterized themselves as having greater self-esteem than did low-low androgynous subjects (Spence et al., 1975).

The Masculinity and Femininity scales from Gough and Heilbrun's (1965) ACL are much more closely related to the corresponding Bem scales than they are to traditional masculinity-femininity measures. In addition to being highly correlated with the Bem scales, the ACL Masculinity and Femininity scales exhibit the same pattern of correlations with interpersonal variables. Thus, it seems appropriate to characterize subjects who score high on both scales as psychologically androgynous (Heilbrun, 1976).

When the 16-variable interpersonal profiles of sex role groups were compared on profile variability, sex differences were again found between androgynous groups. Androgynous males had a relatively flat profile of interpersonal variables that stood in contrast to the profile of stereotyped males that spiked on sex role stereotyped variables. Androgynous

females had a variable profile that was a mirror image of the sex role stereotyped profile for stereotyped females. Such a finding does not necessarily warrant the conclusion that androgynous males are more "flexible" in their interpersonal behavior than androgynous females. The greater profile variability of androgynous females may reflect a more differentiated self-perception on their part. Whether or not such differences in self-report are reflected in behavior is, of course, still an open, empirical question.

Comparing the Empirical Validity of the Standard Form with Two Abbreviated MMPIs

Charles S. Newmark and David R. Ziff
University of North Carolina School of Medicine

Alfred J. Finch, Jr.
Virginia Treatment Center for Children
Richmond

Philip C. Kendall
Virginia Commonwealth University

The standard form Minnesota Multiphasic Personality Inventory (MMPI) and two abbreviated forms, the MMPI-168 and the Faschingbauer Abbreviated MMPI (FAM), were compared with direct measures of psychopathology obtained from the Brief Psychiatric Rating Scale (BPRS) with psychiatric inpatients. Each patient was interviewed using the Mental Status Schedule by one rater while another rater observed this initial diagnostic interview behind a one-way mirror. Thus, each patient was rated on the BPRS by two raters to assess interrater reliability. Since MMPI scales contain more than one interpretative factor, these scales were correlated with the means of more than one BPRS symptom using multiple correlation coefficients. The multiple correlation coefficients between the BPRS ratings and the corresponding MMPI and abbreviated-form scales were significantly high and comparable. Only on *Pd* for females did a significant difference occur, with the FAM correlation being significantly higher. These findings suggest that these abbreviated forms are an accurate substitute for the standard-form MMPI in predicting objective measures of psychopathology.

The recent development of several abbreviated forms of the Minnesota Multiphasic Personality Inventory (MMPI) has precipitated a plethora of investigations assessing the practical utility of these instruments. The majority of these studies focused solely on comparisons with the standard MMPI of group mean data and individual profile pairs concerning validity, high points, general elevations, code-type correspondence, configural analyses, and application of various MMPI-derived diagnostic rules. Of the six abbreviated MMPIs now available for clinical use, namely Kincannon's (1968) Mini-Mult, Dean's (1972) Midi-Mult, Hugo's (1971) Short Form, Faschingbauer's (1973) Abbre-

viated MMPI (FAM), Overall and Gomez-Mont's (1974) MMPI-168, and Spera and Robertson's (Note 1) Maxi-Mult, only the FAM and the MMPI-168 have been demonstrated to predict accurately both individual and group mean data with both normal and psychiatric samples (Newmark, Boas, & Messervy, 1974; Newmark, Cook, Clarke, & Faschingbauer, 1973; Newmark, Galen, & Gold, 1975; Newmark & Glenn, 1974; Newmark, Newmark, & Cook, 1975; Newmark, Newmark, & Faschingbauer, 1974; Newmark, Owen, Newmark, Cook, & Faschingbauer, 1975; Newmark & Raft, 1976).

None of these investigations, however, has dealt with two crucial issues. First, Is the interpretation obtained from an abbreviated form comparable to that obtained from the standard form? If not, regardless of whether individual and group mean data are comparable, the abbreviated form should not be used. Therefore, the comparative interpretive efficacy of the FAM and the standard MMPI

Requests for reprints should be sent to Charles S. Newmark, Department of Psychiatry, University of North Carolina Medical School, Chapel Hill, North Carolina 27514.

Philip C. Kendall is now at the University of Minnesota.

was assessed with a sample of psychiatric inpatients (Newmark, Conger, & Faschingbauer, 1976). Psychiatric residents evaluated the accuracy of the interpretation of both test forms for each of their patients. Although significantly higher mean ratings resulted for the standard MMPI, when data were collected across sexes, the quantity of loss was significantly lower than expected. That is, the FAM functioned as an instrument 80% as long as the standard MMPI, even though it contains only 30% of the items.

Newmark, Falk, and Finch (1976) also compared the interpretive accuracy of the standard MMPI and three abbreviated forms with a sample of psychiatric inpatients. Although significantly higher mean ratings resulted from the standard MMPI when compared with either the FAM or Hugo's Short Form, comparable ratings by psychiatric teams were obtained when comparing the MMPI-168 and the standard-form MMPI interpretations. Two major limitations of these latter two studies include the use of psychiatric judges as the validity criterion and the failure to have the interpretations done by computer to reduce the error factor introduced by clinical judgment.

A second and more crucial issue concerns the empirical validity of the standard and abbreviated forms when compared with direct measures of psychopathology. In previous investigations the utility of the abbreviated form has been based on concurrent validity with the standard form of the MMPI. Thus, though the FAM may predict the standard-form MMPI more precisely than the MMPI-168 does, the MMPI-168 might predict psychopathology more accurately than either the FAM or standard-form MMPI.

The present investigation attempted to compare the empirical validity of two abbreviated forms of the MMPI and the standard form with direct measures of psychopathology using psychiatric inpatients. This investigation seems necessary, since there is no reason to use an alternative version of a psychometric instrument, whether longer or shorter, unless it possesses greater empirical validity than the form it replaces or unless it is significantly less expensive to administer with

no loss in empirical validity. Rand (1976) and Overall, Higgins, and De Schweinitz (1976) independently concluded that using external criteria is a vital prerequisite for evaluating abbreviated forms of the MMPI.

Method

Subjects

The subjects were 158 male and 217 female consecutive admissions to either a private or a university psychiatric inpatient facility. For numerous reasons, primarily invalid profiles, lack of cooperation, confusion, limited intellectual ability, and cerebral dysfunction, 38 males and 47 females were eliminated from this investigation. The resultant 120 males and 170 females were between the ages of 17 and 65 years ($M = 34.7$), and their level of education ranged from 3 to 22 years ($M = 10.2$). First admissions to a psychiatric hospital comprised 71% of the sample. Although there were no significant educational differences as a function of sex, the female patients were significantly older ($p \leq .05$).

Apparatus

The Brief Psychiatric Rating Scale (extended version). The rating scale that was used to record clinical observations in this investigation was a 42-item instrument devised by Pokorny, in collaboration with Overall and others, for use in a survey of the Texas state hospital population (Pokorny & Overall, 1970). It consists of the widely used 18-item Brief Psychiatric Rating Scale (BPRS; Overall & Gorham, 1962) plus 24 additional rating constructs from various syndrome scales chosen to span the range of lesser psychopathologies. Each symptom construct in the BPRS, and in the extended version used here, is rated on a 7-point scale of severity. Approximately half of the BPRS ratings are based on observations of the patients, their modes of communication, and the organization of their mental processes without regard to specific content. Information regarding the development, scoring procedure, reliability, and validity of this instrument can be found elsewhere (Overall & Gorham, 1962; Overall & Klett, 1972).

The BPRS was chosen as the criterion variable in this investigation, since it has been used fruitfully for the isolation and identification of psychopathological syndromes and categories in numerous studies (Auerbach & Ewing, 1964; Overall, 1974; Overall, Hollister, Johnson, & Pennington, 1966; Overall, Hollister, & Pichot, 1967; Pokorny & Overall, 1970; Steer, 1974) and because the practical utility of rating scales as objective measures of psychopathology has been extensively documented (Lorr, 1954; Norton, 1967; Schreier, Reznikoff, & Glueck, 1962; Wittenborn, 1972). Furthermore, the BPRS has symptom labels similar to those found on the

MMPI scales. The development of rating scales in an attempt to standardize, fractionate, and objectify the process of clinical decision making has been among the most significant achievement in psychodiagnosis during the past decade (Goldberg, 1974). That behavioral rating scales have largely supplanted psychological tests as criterion measures has been discussed recently by Cleveland (1976).

The Mental Status Schedule. To complete the BPRS, Overall and Gorham (1962) advocated the use of an 18-minute generally nondirective interview. However, this interview proved impractical in the present investigation due to its brevity and lack of structure and because the usefulness of rating scales has been shown to be limited when there is significant variability in the interview procedures on which the ratings are based (Spitzer, Fleiss, Burdock, & Hardesty, 1964). Therefore, the Mental Status Schedule (MSS), which was developed by Spitzer, Burdock, and Hardesty (1964) to provide a standardized interview to assess the major dimensions of the mental status in which the content and order of questions are fixed, was used in this investigation.

The MSS contains an interview schedule and a matching inventory of 248 dichotomous items descriptive of small units of psychopathological behavior that the interviewer evaluates as true or false. The inventory was not used in this study. The interview schedule is a series of 82 questions arranged in a definite sequence to provide a natural progression of topics that cover a wide range of psychopathology that the interviewer uses to elicit information from the patient. Fifty-one supplementary questions were provided to clarify or probe the areas in which the patient's responses seemed incomplete. The schedule provided alternative phraseology for many questions so that the examiner could ask the question in the form and tense most appropriate to the circumstances. Thus, even though standardized, the procedure has enough flexibility so that when properly administered it seems like a typical clinical interview, allowing good rapport between interviewer and patient (Spitzer, Fleiss, Kernohan, Lee, & Baldwin, 1965). The items on the inventory were developed by surveying standard psychiatric texts and by interviewing several hundred psychiatric patients with preliminary forms of the MSS to obtain a comprehensive coverage of overt signs of psychopathology. Efforts were made to word the questions so that even inpatients with minimal education or psychological insight could comprehend them. The length of the interview varied from 20 to 60 minutes depending on the patient's verbal productivity, amount of psychopathology present, and cooperation. A detailed description of the MSS as well as information bearing on the reliability, validity, and administration of this instrument can be found elsewhere (Spitzer, Endicott, & Cohen, 1964; Spitzer, Fleiss, Burdock, & Hardesty, 1964; Spitzer, Fleiss, Endicott, & Cohen, 1967).

The advantages of the MSS over other commonly used assessment procedures include the incorporation of a standardized interview schedule to reduce in-

consistency and oversight due to variability in interviewing technique and coverage of psychopathology, awareness of what questions are asked to provide a framework within which the patient's responses can be understood by others not present at the interview, and the use of a score sheet that serves simultaneously as a permanent clinical record and as a form for automated data processing. The use of the same interview schedule for all patients also has the research advantage that differences observed among patients tend to reflect actual differences rather than artifacts caused by differences in areas of psychopathology explored or interviewing techniques used.

Procedure

Subjects were tested approximately 48 to 72 hours after admission as part of the routine screening procedure. A counterbalanced design was used to offset evidence of decreased pathology under repeated MMPI administrations (Kincannon, 1968; Newton, 1971; Windle, 1954). The subjects were assigned alternatively to one of two groups: one group initially received the MMPI, and the other received either the FAM or the MMPI-168. As soon as possible after completion of this initial testing, the procedure was reversed so that each subject received both the standard and one abbreviated MMPI form. Thus, independently administered abbreviated forms were obtained, since the extracted method possessed inherent flaws. Most notably, a perfect reliability of scores was assumed, since the same items scored were used on both the abbreviated and standard forms. Furthermore, Newmark et al. (1973) presented evidence that the extracted form has limited benefits.

The FAM was scored and converted into standard-scale raw scores using Fashingbauer's (1973) tables of conversion for each sex. Conversion of prorated raw scores to *T* scores was then accomplished following the standard procedures. The MMPI-168 was scored and converted into standard-scale *K*-corrected raw scores using regression equations for each scale as derived by Overall and Gomez-Mont (1974). *K*-corrected *T* scores were used in this study in order to be consistent with the literature. The standard-form MMPI answer sheets were hand scored in the traditional manner. Invalidity was defined as either $F \geq 90$, L or $K \geq 70$ or $? \geq 60$.

Four raters, consisting of two clinical psychologists and two psychiatric residents, were presented detailed operationally defined explanations of the symptoms on the BPRS as defined by Overall and Gorham (1962) and Porkorny and Overall (1970) in an attempt to reduce idiosyncratic biases. Whereas definitions can never be rigorous or complete except in mathematics, they nevertheless serve to demarcate a concept even though its boundaries remain somewhat blurred (Zubin, 1967). All raters had at least 4 years of diagnostic experience. Such a procedure was necessary because it has been demonstrated (Kreitman, 1961) that variables relating to

nomenclature and degree of experience were the greatest impediments to reliability in psychiatric diagnoses. Clearly definable terms and equivalent diagnostic experience are essential.

Initially, in an attempt to maximize interrater reliability, filmed MSS interviews with three psychiatric inpatients, with varied degrees and types of psychopathology, were presented to the four raters. Following each filmed presentation a detailed discussion of the rating differences occurred. That such a procedure has merit in increasing rater reliability has been confirmed by Raskin, Schulterbrandt, and Reatig (1966).

Each patient was then interviewed using the MSS by one of the raters while another rater observed this initial diagnostic interview behind a one-way mirror. Neither rater was familiar with the patient's history or observed ward behavior. Reliability is definitely enhanced if two raters observe the same interview rather than each rater observing a separate interview (Wittenborn, 1972). Thus, each patient was rated on the BPRS by two raters so that interrater reliability was assessed. Immediately following the interview, each rater recorded his observations independent of his colleague's rating.

When two raters observe the same patient, two distinct strategies exist for combining data (Overall, 1968). One approach has been to have both observers discuss each rating at the conclusion of the interview and to arrive at a consensus rating. The other more frequently used model has been to have raters complete ratings independently and then to average the ratings on the theory that random errors tend to cancel. This latter model has been

shown to be an advantageous procedure by Overall, Hollister, and Dalal (1967). Consequently, the mean ratings for each BPRS symptom were used.

Since several MMPI scales contain more than one interpretative factor, these scales were correlated with the means of more than one BPRS symptom rating using multiple correlation coefficients (Bruning & Kintz, 1968). Only for Scale *L*, which was correlated with only one BPRS symptom, was a product-moment correlation used. The MMPI scales and the corresponding BPRS scales with which they were correlated were as follows: *L*-Denial; *F*-Unusual Thought Content, Conceptual Disorganization, Intellectual Subnormality; *K*-Denial, Guardedness; *Hs*-Conversion Somatization, Somatic Concern; *D*-Depressive Mood, Introjection of Blame; *Hy*-Conversion Somatization, Dramatization, Manipulativeness, Denial, Emotionally Labile; *Pd*-Antisocial Trends, Impulsiveness, Projection of Blame, Hostility, Manipulativeness; *Mf*-Sexual Crossed Identification, Passive Dependency; *Pa*-Suspiciousness, Projection of Blame, Hostility; *Pt*-Anxiety, Tension, Guilt Feelings, Phobias, Compulsive Acts, Obsessive Thoughts; *Sc*-Conceptual Disorganization, Unusual Thought Content, Sexual Inadequacy, Emotional Withdrawal, Blunted Affect, Feelings of Unreality; and *Ma*-Excitement, Elevated Mood, Grandiosity, Tension. The BPRS ratings selected for inclusion were based on item analyses content and interpretive data of the MMPI scales as presented by Dahlstrom, Welsh, and Dahlstrom (1972), Fowler (1966), and Lachar (1974).

Results

The *T*-score means, standard deviations, Pearson product-moment correlations, and *t* values of the comparable validity, clinical, and *Mf* scales of both the MMPI and the FAM are presented as a function of sex in Table 1. Note that in most cases for both males and females the standard deviation was larger for the FAM than for the comparable standard MMPI scales. Statistical analysis showed this to be a significantly reliable trend ($p \leq .05$).

Paired *t* tests yielded significant mean differences on *L*, $t(59) = 2.87$, $p \leq .01$, for males, and on *F*, $t(84) = 3.74$, $p \leq .001$; *Hs*, $t(84) = 3.17$, $p \leq .01$; *Pa*, $t(84) = 3.29$, $p \leq .01$, and *Pt*, $t(84) = 3.42$, $p \leq .001$, for females. In all cases the FAM significantly overestimated the MMPI scale scores. This finding is consistent with previously published results (e.g., Newmark et al., 1973), demonstrating that the FAM seemed to overestimate slightly MMPI scale means.

For males, scale correlations ranged from .82 for *L* to .93 for *K* and *Hs* ($M = .88$, $Mdn = .89$). For females, correlations ranged from .83 on *Pd* to .95 on *F*, *Hs*, *D*, and *Ma* ($M =$

.91, $Mdn = .93$). All correlations were significantly different from zero ($p \leq .001$).

The *T*-score means, standard deviations, and Pearson product-moment correlations of the comparable validity, clinical, and *Mf* scales of both the MMPI and the MMPI-168 are presented as a function of sex in Table 2. Note that in approximately half of the cases for each sex, the standard deviation was larger for the MMPI-168 than for the comparable standard MMPI scale.

Paired *t* tests yielded no significant mean differences for male subjects. For females, however, significant mean differences occurred on *F*, $t(84) = 4.29$, $p \leq .001$; *Pd*, $t(84) = 3.09$, $p \leq .01$; *Pa*, $t(84) = 2.96$, $p \leq .01$; and *Sc*, $t(84) = 4.59$, $p \leq .001$. In all cases the MMPI-168 significantly overestimated the MMPI scale scores. The results for females are rather surprising in view of several previously published reports (Newmark, Newmark, & Cook, 1975; Newmark & Raft, 1976) that found no significant mean differences for a sample of both male and female psychiatric inpatients and medical patients.

For males, scale correlations ranged from .92 on *L* to .98 on *Hs* and *Sc* ($M = .96$, $Mdn = .96$). For females, scale correlations ranged

* $p \leq .01$.

from .89 on *K* to .96 on *D* ($M = .93$, $Mdn = .93$). All correlations were significantly different from zero ($p \leq .001$).

Table 3 presents the multiple correlation coefficients between the BPRS ratings and the corresponding MMPI and abbreviated-form scales. All of the correlations were significantly different from zero ($p \leq .001$). For males, correlations ranged from .61 for *Sc* to .86 for *Hy* ($M = .78$, $Mdn = .81$) on the standard form and from .63 for *L* to .85 for *D*, *Hy*, and *Ma* ($M = .80$, $Mdn = .82$) on the FAM. For females, correlations ranged from .57 for *L* to .84 for *D* ($M = .78$, $Mdn = .79$) on the standard form and from .54 for *L* to .86 for *Hs* ($M = .79$, $Mdn = .79$) on the FAM. With regard to the MMPI and the MMPI-168, for males, correlations ranged from .64 for *L* to .84 for *Ma* ($M = .78$, $Mdn = .81$) on the standard form and from .63 for *L* to .84 for *Hy*, *Mf*, and *Pa* ($M = .79$, $Mdn = .79$) on the MMPI-168. For females, correlations ranged from .61 for *L* to .86 for *Ma* ($M = .79$, $Mdn = .82$) on the standard form and from .64 for *L* to .86 for both *Hs* and *Hy* ($M = .79$, $Mdn = .81$) for the MMPI-168. Only on *Pd* for females did a significant difference occur between the MMPI and the abbreviated-form correlations, $t(84) = 2.72$, $p \leq .01$, with the FAM being

significantly higher. However, this significant difference could occur by chance, since 48 comparisons were made.

Paired *t* tests between the multiple correlation coefficients from the BPRS ratings and each abbreviated form yielded significantly higher correlations for females on *L*, $t(84) = 3.05$, $p \leq .01$; *F*, $t(84) = 2.32$, $p \leq .05$; and *Pt*, $t(84) = 2.07$, $p \leq .05$. For *L* and *Pt*, the MMPI-168 correlation coefficients were higher, whereas for *F* the FAM correlation coefficients were higher. For males, significantly higher correlations occurred for *K*, $t(59) = 2.66$, $p \leq .01$, on the FAM and *Pa*, $t(59) = 2.19$, $p \leq .05$, on the MMPI-168.

Product-moment reliability coefficients across the four raters ranged from .83 to .88 ($M = .86$). Mean interrater reliabilities between the BPRS scores and the corresponding MMPI scale scores were as follows: *L* = .87, *F* = .86, *K* = .84, *Hs* = .88, *D* = .88, *Hy* = .87, *Pd* = .84, *Mf* = .87, *Pa* = .83, *Sc* = .85, and *Ma* = .88. Each rater rated the same number of patients.

Discussion

Although both abbreviated forms significantly overestimated several of the comparable standard MMPI scale means, the actual

mean differences that occurred were extremely small, ranging from .3 to .9, and probably were not of any practical significance. Hill (1976) presented compelling evidence, suggesting that the concepts of statistical validity and clinical utility were by no means identical and that it does not necessarily follow that one is a prerequisite for the other. Furthermore, related *t* tests are concerned with the magnitude of the correlation so that when large correlations, as were obtained in this study, are found, the differences between the means can be extremely small and still be statistically significant.

The majority of abbreviated-form investigations have demonstrated a tendency for these forms to underestimate MMPI *T*-score standard deviations, leading Dean (1972) to suggest that this is somehow inherent in shorter tests. However, Faschingbauer (1976) concluded that his use of a substitution model rather than a regression model in developing conversion values for the FAM would overcome this persistent tendency. Equivocal support for this hypothesis was found in the present investigation, as the FAM had generally larger standard deviations than did the standard-form MMPI, whereas the MMPI-168, which was developed using a regression model, had higher standard deviations for approximately half of the scales for each sex.

The correlations obtained between the standard MMPI and the BPRS ratings were markedly greater than results obtained from other investigations (Endicott & Jortner, 1966, 1967; Endicott, Jortner, & Abramoff, 1969; Harris, Wittner, Koppell, & Hilf, 1970), which correlated other objective measures of psychopathology with various standard MMPI scales. The higher correlations may have occurred in the present investigation due to the use of multiple correlation coefficients, which combine several objective measures of each MMPI scale rather than using just one measure. For example, instead of correlating *Pt* with objective measures of anxiety only, a multiple correlation coefficient was obtained from objective measures of anxiety, tension, guilt, phobias, compulsive acts, and obsessive thoughts.

The correlations obtained between the ab-

breivated forms and the BPRS ratings were significantly high and comparable to the MMPI-BPRS rating correlations. Scale *L* correlations were consistently lower in all cases, possibly because only one objective measure of psychopathology was correlated with it. Only on *Pd* for females did a significant difference occur between the MMPI and the abbreviated-form correlations, with the FAM being significantly higher. However, this difference quite likely could have occurred by chance. Thus, the empirical validity of both abbreviated forms seems comparable to the standard-form MMPI when compared with direct measures of psychopathology.

The FAM-BPRS rating correlations and the MMPI-168-BPRS rating correlations were significantly different in 5 of the 24 comparisons made. However, neither abbreviated form demonstrated any superiority.

The interrater reliabilities obtained in this investigation were comparable to those obtained in the original developmental investigation of the BPRS by Overall and Gorham (1962). However, the present results were somewhat higher than those obtained in the majority of recent BPRS investigations (e.g., Anderson, Kuehnle, & Catanzano, 1976) possibly due to the attempt to maximize interrater reliability through the use of practice procedures as advocated by Raskin et al. (1966).

As an additional analysis, the mean BPRS symptoms rating scores were obtained for each comparable MMPI scale. Both abbreviated- and standard-form MMPIs in each sample as a function of sex were then subgrouped using the mean BPRS ratings as a moderator variable. Means between 0 and 2.5 were included in the low-ratings group, and means between 3.5 and 6.0 were included in the high-ratings group. Means from 2.6 to 3.4 were excluded to provide more well-defined groups. The mean MMPI scale scores for the low-ratings group and high-ratings group were not significantly different from the mean abbreviated-form scales for the low-ratings and high-ratings groups, respectively, within both samples regardless of sex.

Endinger, Kendall, Hooke, and Bogan (1976) emphasized that in the absence of in-

dependent validation, none of the abbreviated forms developed can be recommended for clinical use. However, there is evidence from the present investigation that both the FAM and MMPI-168 were comparable to the standard-form MMPI when compared with direct measures of psychopathology. Since both abbreviated forms are slightly less expensive to administer and result in more completed profiles with no loss in empirical validity, they appear to be an adequate substitute when administration of the standard-form MMPI is not feasible.

Treatment of Female Sexual Dysfunction Through Symbolic Modeling

Georgia H. Nemetz, Kenneth D. Craig, and Gunther Reith
University of British Columbia, Vancouver, Canada

An evaluation of treatment programs for women suffering from debilitating sexual anxiety is described. Attitudinal and behavioral indices of sexual adjustment and sexual anxiety were obtained from 22 women to assess effects of individual and group graduated symbolic modeling through videotapes, with concurrent behavioral tasks as treatment procedures. All women serving as clients had reported severe anxiety that precluded sexual enjoyment or activity. Sixteen clients were randomly assigned to two groups receiving either individual or group treatment. Treatment consisted of relaxation training followed by viewing 45 videotaped vignettes depicting graduated sexual behaviors. Five sessions were held twice weekly. The other 6 women were subjected to identical measurement without the benefit of treatment. Decreases in anxiety and increases in behavioral and attitudinal measures were evidenced; however, a trend toward greater improvement was observed for those receiving group treatment. Improvement remained stable through a 1-year follow-up. Control clients showed no improvement and trends toward deterioration. The treatment regimen appeared to produce positive changes in attitudinal, behavioral, and anxiety indices simultaneously.

Sexual anxiety continues to be a major concern for therapists concerned with sexual dysfunction and anomalies. Although a diversity of therapeutic techniques have been devised to accommodate the numerous theoretical positions (Kaplan, 1974; Masters & Johnson, 1970), there is general agreement that anxiety toward sexual functioning is a basic prohibitive factor in the enactment and enjoyment of sexual activity. As anxiety, whether defined or measured affectively, behaviorally, or physiologically, is a highly learnable pattern of response, aversive sexual incidents would be sufficient to generate female sexual dysfunction. These "incidents" can range from rape and parental molestation to anxiety-inducing instruction from others, failure to achieve "expected orgasm," and pre-occupying concern with physical attributes. For instance, Masters and Johnson (1970) conceptualized performance anxiety and spec-

tating as the two major inhibiting factors to the natural flow of stimuli leading to the female orgasmic response. Because anxiety is readily attached to previously noneliciting stimuli on the basis of simple contiguity, the full range of sexual behavior may become affected. For example, anxiety toward intercourse may generalize sufficiently to disrupt or preclude other effective sexual habits.

A number of therapists have effectively used the desensitization paradigm (Wolpe, 1958) to reduce sexual anxiety and achieve a concurrent increase in pleasurable sexual behavior (Brady, 1966; Kraft & Al-Issa, 1967; Lazarus, 1963). Lazarus (1963) treated 16 inorgasmic women described as recalcitrant and persistent cases. Subjects were instructed in progressive relaxation, hierarchies with respect to sexual functioning were constructed, and anxiety-eliciting items were presented verbally in a hierarchical fashion. Lazarus reported that 9 patients became "sexually adjusted" after a mean of 28.7 sessions over an average period of 6 months. Control group data were not provided. Kraft and Al-Issa (1967) used desensitization for a

female patient whose dysfunction was attributed partially to social anxiety in heterosexual situations. The authors reported complete recovery after 84 1½-hour systematic desensitization sessions. Variations in traditional desensitization procedures have also proven effective. Clopton and Risbrough (1973) reported success in eliminating sexual anxiety and in inducing approach behavior by having patients present sexually aversive stimuli to themselves at or before masturbation-induced orgasm. Brady (1966) reported success for 4 out of 5 clients suffering from "chronic severe frigidity" using desensitization aided by the use of subanesthetic doses of methohexital sodium as a means of producing profound muscular relaxation.

The therapeutic procedures used in the present investigation were based on modeling strategies because of their effectiveness in reducing maladaptive fears and avoidance behavior and in concomitantly inducing desirable behavior. Elements of vicarious extinction (Bandura, Grusec, & Menlove, 1967; Craig, Best, & Ward, 1975), graduated symbolic modeling (Bandura, Blanchard, & Ritter, 1969), and videotaped desensitization (Wincze & Caird, 1976; Woody & Schauble, 1969) were utilized. Potential effects of modeling therapies, previously identified (Bandura, 1969), include the acquisition of previously nonexistent patterns of behavior, weakening response inhibitions, and facilitating the occurrence of preexisting responses in the behavior repertoire. In the instance of sexual anxiety, modeling therapy would appear to be particularly promising because of its effectiveness in extinguishing anxiety and avoidance tendencies and in inducing behavioral and attitudinal change. Bandura et al. (1969) found graduated symbolic modeling to be more effective than standard desensitization in neutralizing the anxiety-arousing properties of snakes and in inducing the greatest behavioral and attitudinal change.

The present study used symbolic modeling through the medium of a videotaped, graduated hierarchy of sexual scenes. Concurrent behavioral tasks also were utilized in the form of homework assignments to match the

scenes portrayed in the videotapes. It was expected that reducing sexual anxiety by vicarious extinction would enable the client to successfully complete the behavioral tasks, thus exposing them to a potentially positive sexual experience. The treatment procedures were based on those used by Wincze and Caird (1976), who found that videotaped desensitization was more effective than standard desensitization in reducing heterosexual anxiety in those suffering from primary sexual dysfunction. The present study extended these treatment procedures to a group therapy program, used additional measurement procedures to examine other components of the behavior change process, and provided a 1-year follow-up of treatment effectiveness.

In addition to the potential that symbolic modeling techniques have for effective intervention, they introduce economies by reducing requirements for therapist involvement—thus making therapy more readily available. In the extreme, the technique can be exclusively self-administered. The procedure also lends itself to application to several clients at the same time. We could find no accounts of videotape treatment used in a group format in the literature. The present study contrasted individual treatment, group treatment, and a waiting list control group.

A multidimensional model for evaluating treatment effectiveness was adopted. Changes in subjective affect were evaluated through self-report scales. Behavioral indices of changes in sexual activities were provided by clients who self-monitored during baseline, treatment, and follow-up phases and by the clients' male partners, who also provided data during these phases of the treatment program. Repetition of the measures, especially the behavioral indices, was designed to assess how rapidly treatment effects would manifest themselves. Because of the potential for producing a reorganization of attitudes toward personal and general sexual behavior, scales evaluating this domain also were included.

Method

Subjects

The subjects were 22 inorgasmic female clients, 15 of whom would satisfy Masters and Johnson's

(1970) criteria for secondary orgasmic dysfunction and 7 of whom would be classified as primary inorganic. All had been referred by physicians to the Sexual Dysfunction Clinic at the Health Sciences Center Hospital at the University of British Columbia. Other selection criteria included presence of anxiety or discomfort toward sexual behavior as measured both by interview data and scores on the Sexual Anxiety Card Sort (Barlow, Leitenberg, & Agras, Note 1); absence of organic causal factors, as established through gynecological examination; absence of acute marital problems justifying inference of an unstable relationship with the sexual partner; and availability and cooperation of the husband or a steady male partner. Of 29 women initially interviewed, 7 failed to score above a cutoff point of 13 out of 100 on the Sexual Anxiety Card Sort. The subjects ranged in age from 21 to 39 years with a median of 26.7 years. Fifteen of the subjects were married, 4 were single, and 2 were separated. The first 16 subjects obtained by successive admissions to the clinic were randomly assigned to one of the two treatment conditions. The last 6 successive admissions were assigned to the control condition. These control subjects were advised truthfully that treatment was not available for approximately 6 weeks but that it would be provided on termination of other clients. All 6 volunteered to participate in pretreatment investigations and provided data on the measures matching those used by experimental subjects. At the end of this period of time, all were treated in this clinic.

Measures

Measures of anxiety included (a) the sexual anxiety Card Sort (Barlow et al., Note 1), which consists of 25 separate cards, describing various sexual behaviors, ranging from mere physical proximity to intercourse and orgasm, that are sorted by the client according to the levels of anxiety induced if she were to engage in the depicted behaviors. The cards are sorted into five categories with scores assigned to them ranging between 0 and 4. Initial admission scores for clients ranged between 13 and 70 with a median of 32. This measure was administered at the initial interview, prior to each of the five treatment sessions, at the 3-week follow-up, and at the 1-year follow-up. (b) On the Bentler Heterosexual Behavior Hierarchy (Bentler, 1968), clients rate 25 statements describing sexual behavior on a scale of 0 to 4 with the extremes labeled *no anxiety* and *very much anxiety*. As this measure contains novel sexual items not depicted in the modeling hierarchy, it was viewed as an indicant of treatment generalization. The Bentler scale was administered at the initial interview, at the 3-week follow-up, and at the 1-year follow-up.

The behavioral measures were based on a sexual behavior index, constructed for this study to measure the incidence of specific sexual behaviors. This instrument requires a recording of the frequency of

nine explicit categories of sexual behavior (see Table 1). Both partners independently record the frequency of their sexual behaviors corresponding to these categories for complete weeks, including 1 week prior to treatment, the intervals between each treatment, during the 3-week follow-up period, and during the week prior to the 1-year follow-up.

Attitudinal measures examining both global and specific sexual attitudes were (a) Rotter's Sex Attitude Scale (Rotter, Note 2), which contains 100 items requiring ratings of attitudes on sexual issues concerning sex roles, sex education, and marital relationships. The measure was administered at the initial interview, prior to the fifth treatment session, and at the 3-week follow-up. (b) The Sexual Semantic Differential assesses attitudes toward specific sexual concepts. Nine of the bipolar scales were based on the Marks and Sartorius (1968) measure. Ratings were scored for two basic dimensions, evaluation and anxiety. Clients rated seven concepts including both specific sexual activities and basic sexual descriptors (see Table 1). The semantic differential was administered at the initial interview, each of the five treatment sessions, the 3-week follow-up, and the 1-year follow-up.

Procedure

At an initial interview, after acceptance into the treatment program, both partners were advised of procedures and regulations. The male's supportive potential was established, and he was instructed to refrain from initiating sexual activity for the duration of treatment. The different measures were described, and questionnaires were completed. The rationale for relaxation training was explained to the client, and she received a tape-recorded or card-form summary of progressive relaxation procedures. She was instructed to practice the exercises twice a day during sessions of approximately 15 minutes.

Five sessions twice a week with 3-day intersession intervals were planned for members of the individual and group treatment conditions. Uncontrollable events such as illness and canceled appointments frequently rendered this schedule unattainable. Procedures for clients receiving group and individual treatment did not differ. Group clients were not encouraged to discuss the program, problems, or progress with each other, and opportunities to do so were kept at a minimum. These clients were informed that group treatment permitted us to work with more than one person. Although some of the clients expressed initial concern over the lack of privacy, none refused to participate, and it was not a continuing problem. Each session began with clients completing the Sexual Anxiety Card Sort and providing the previous week's sexual behavior indices. Subjects were then taken into a soundproof room for a videotape session. They were made comfortable in a reclining chair and were instructed to relax while listening to a relaxation tape for approximately 15 minutes. While the sexual scenes

** $p < .01$.

were on, clients were instructed to visualize both themselves and their partner engaging in the depicted behaviors. During intervals between scenes, they were to utilize whatever relaxation technique they found beneficial. Clients were provided with the option of terminating the scenes by signaling anxiety to the therapist if necessary.

Instruction was provided for the Wolpe (1958) subjective units of distress scale, and distress was to be signaled if the client rated her feelings at greater than 15 units. No client exercised this option. Each of 45 vignettes was presented in brief, with progressively longer portions and relaxation episodes interspersed between them. The 4-min vignettes were presented progressively for 15, 30, 30, 45, 60, and 60 sec with 30-sec pauses between episodes for relaxation. Eight vignettes were shown per session. Viewing sessions lasted approximately 1 hour. After completion, clients filled out the Sexual Semantic Differential. At the end of the session, they were instructed to practice the viewed activities at home with their partners.

At the 3-week follow-up, both partners were interviewed, behavioral indices were collected, questionnaires were readministered, and a standard inquiry into the treatment and personal progress was completed. At the 1-year follow-up, clients were contacted by telephone. All questionnaires, excluding the Rotter Sex Attitude Scale, were readministered.

Subjects assigned to the control condition were told that treatment would not be available for approximately 6 weeks, but they were asked to participate in pretreatment investigations. None of the six women refused, hence all came to the clinic on the same schedule as treatment clients and provided complete accounts of their sexual behavior on the various measures. Male partners in this condition also completed all the sexual behavior indices. Because control group clients were provided with treatment in a different program after time comparable to that required by the treatment groups at the 3-week follow-up interval had elapsed, they were not included in the 1-year follow-up assessment.

Results

The following provides the outcome of analyses on anxiety, behavioral, and attitudinal measures for the duration of treatment and the 3-week and 1-year assessments. Basic analyses of initial treatment effects used a two-way analysis of variance with the two treatment groups and the control condition comprising the three levels of the between-groups factor and the baseline, five process, and 3-week follow-up administrations providing the within-groups factor. Analyses of the 1-year follow-up data used a two-way analysis of variance contrasting the two treatment groups as a between-subjects factor and the four occasions during which data were collected as a repeated measures factor. These were baseline, the fifth treatment session, the 3-week follow-up, and the 1-year follow-up. Significant main effects and interactions were analyzed further using Cicchetti's (1972) version of the Tukey multiple range comparison technique ($\alpha = .05$). Table 1 summarizes the findings for the anxiety, attitudinal, and behavioral measures.

Anxiety Measures

As noted in Table 1, significant main effects and interaction effects for groups over

time were observed for the three anxiety measures. (See Table 2 for mean group frequencies at selected sessions.) Post hoc comparisons on the card sort data indicated that for both treatment conditions, the 3-week follow-up measure differed significantly from the pretest measure as well as from treatment measures at Sessions 1, 2, and 3. There were no differences between measures for the control condition. Post hoc comparisons for the individual assessment sessions indicated that all three groups differed on the pretreatment measure, but the difference disappeared with respect to the individual and group treatment comparison while doubling in magnitude with respect to the differences between both treatment conditions and the control condition. As the premeasures were significantly different, the data were subjected to an analysis of covariance with the premeasure as the covariate. Results indicated significant treatment effects, $F(2, 17) = 4.40, p < .05$, a time effect, $F(5, 85) = 12.81, p < .01$, and a Treatment \times Time interaction, $F(10, 85) = 6.33, p < .01$, indicating that the results were due to treatment over time and not to the initial premeasure difference.

Data for the semantic differential anxiety dimension, obtained by collapsing over the sexual concepts, revealed unfavorable anxiety during the baseline in all groups, with

Table 2
Mean Frequencies for Anxiety Measures

Measure	Baseline	Session 5	3-week follow-up	1-year follow-up
Anxiety Card Sort				
Individual	32.25	12.87	8.00	15.19
Group	22.14	12.42	6.42	9.29
Control	41.66	40.00	45.66	—

Group	-8.85	7.85	20.14	22.61
Control	-21.00	-18.66	-18.00	—

Note. A dash indicates that the measure was not given at this time.

the treatment groups improving over time until their ratings of the concepts became favorable. The control group initially improved but subsequently declined back to baseline levels. Post hoc analyses indicated that within the two treatment conditions, the follow-up measure differed significantly from the pretreatment and first and second treatment measures. Within each administration period there were no differences between conditions until Sessions 4 through follow-up, at which time the treatment conditions differed from the control condition but not from each other. As with the Sexual Anxiety Card Sort, the decline in anxiety in the treatment conditions manifested itself at the time of the third treatment session.

Findings using the Bentler Heterosexual Behavior Hierarchy were similar, even though this measure was not administered during treatment sessions. For both treatment conditions the follow-up measure was significantly below the baseline measure. The control condition showed no change.

Analyses of the 1-year follow-up data for all three anxiety measures indicated that the two treatment conditions did not differ from each other ($p > .05$), but the effect for the time of administration of the measure was significant. This was the case for the card sort, $F(3, 12) = 25.20$, $p < .01$, the semantic differential, $F(3, 12) = 9.38$, $p < .01$, and the Bentler hierarchy, $F(3, 12) = 9.39$, $p < .01$. Post hoc comparisons indicated that the 1-year follow-up data differed significantly from the baseline measure but not from treatment termination or the 3-week follow-up. Thus, the reduction in anxiety displayed at treatment termination and the 3-week follow-up was maintained.

Behavioral Measures

Clients' and partners' reports for the different categories of the sexual behavior index were intercorrelated to evaluate reliability. Following z-score transformations, an overall mean intercorrelation of .912 was obtained, indicating good reliability. The following provides details on the clients' data only.

Treatment influenced the extent to which

the women initiated sexual behavior with their partners, as indicated by the significant Group \times Time interaction. Consistent with the means reported in Table 3, post hoc pairwise comparisons indicated that clients in the two treatment conditions reported increases in the number of female initiatives, whereas the no-treatment control condition actually declined over the 6 weeks of monitoring. These effects were maintained throughout the year preceding the 1-year follow-up, as indicated by a main effect for the four measurement periods, $F(3, 12) = 6.55$, $p < .01$, without differences between the 3-week and 1-year follow-up data. The two treatment groups did not differ at the 1-year follow-up.

Treatment effects over time were also observed for three of the five measures of pre-coital sexual interaction. With respect to visual sexual behavior, post hoc comparisons of the significant Treatment \times Time interaction indicated that clients in the two treatment conditions maintained stable rates of visual exposure to their partners, and the no-treatment control groups actually declined in the frequency of visual exposure over the 6 weeks of behavioral monitoring.

Analyses of long-term effects for visual sexual exposure revealed that neither of the two treatment groups differed from the rate of visual exposure observed at the 3-week follow-up. However, the two groups did differ significantly from each other at that time, with the group treatment exceeding the individual treatment, $F(1, 12) = 8.25$, $p < .01$.

Nonsexual sensate focus effects were apparently the result of those clients receiving group treatment engaging in significantly more nonsexual sensate focus, relative to the baseline measure, whereas clients in the no-treatment control actually experienced a significant decrease in the monitored behavior. Clients in the individual treatment condition maintained a fairly steady rate of nonsexual sensate focus.

The results of the 1-year follow-up for nonsexual sensate focus indicated that the two treatment groups did not display any significant change over the follow-up period ($p > .10$).

Post hoc comparisons indicated that both

Note. A dash indicates that the measure was not given at this time.

treatment groups displayed initial increases in the frequency of sexual sensate focus that were sustained throughout treatment and during the first week of follow-up. However, the individual treatment clients declined thereafter relative to the group treatment clients. The control group maintained a relatively stable incidence of sexual sensate focus throughout the 6 weeks of self-monitoring, and, at the time of the 3-week follow-up, they reported significantly lower levels than either of the two treatment groups. The in-

creased incidence of sexual sensate focus was maintained from the 3-week to the 1-year follow-up, with the two treatment groups not changing over this interval ($p > .10$) and not differing from one another at that time.

Analyses of clients' reports of the incidence of foreplay lasting longer than 1 minute but less than 10 minutes indicated a significant main effect for treatment, with subsequent post hoc comparisons indicating that the two treatment groups differed significantly from the control group but not from each other.

Inspection of the data indicates a very high incidence of 10 minutes of foreplay in the group treatment clients' reports during the baseline period. At the time of the 1-year follow-up, the two treatment groups maintained the incidence reported at the 3-week follow-up.

Analyses of the incidence of foreplay lasting between 10 and 20 minutes also indicated significant treatment effects but no interaction with time. Paired comparisons of the main effect indicated that the two treatment groups reported a greater incidence than the control group, but they did not differ from one another. No initial differences were observable in the baseline measure. There were no differences between the 3-week follow-up and the 1-year follow-up, indicating that the beneficial effects of treatment had been maintained.

Analyses of the incidence of intercourse were restricted to differences between the baseline and 3-week follow-up measures because clients and their partners had been enjoined to avoid intercourse throughout treatment. Results indicated significant treatment and Treatment \times Time interaction effects. Post hoc comparisons indicated that the significant Time \times Treatment interaction apparently was the result of an increased frequency of intercourse relative to baseline for those clients receiving group and individual treatment as compared to a decline in incidence as reported by the no-treatment controls. At the time of the 1-year follow-up, post hoc analyses of a significant interaction between groups and time, $F(3, 12) = 10.77$, $p < .01$, indicated that the group receiving individual treatment maintained the level of intercourse observed at the time of the 3-week follow-up. However, group treatment led to significant increases relative to both the individual treatment group and the incidence of intercourse reported at the time of the 3-week follow-up.

Analyses of the incidence of orgasm reported by the women yielded no significant effects for treatment or the interaction of time with the treatment condition. Reports of the incidence of orgasm were at the zero level for the control group and were only marginally greater for either of the two treat-

ment groups. At the end of the 1-year follow-up, there was a nonsignificant tendency for both treatment groups to increase in the incidence of orgasm relative to the baseline, treatment termination, and 3-week measures, $F(3, 12) = 1.23$, $p > .10$.

Attitudinal Measures

The Rotter Sex Attitude Scale was administered to evaluate global sexual attitudes, and a semantic differential had been constructed to examine the evaluative dimension with respect to specific sexual concepts. Data from the Adjusted-Maladjusted subscale of the Rotter measure were subjected to a two-way analysis of variance, with the treatment groups and control condition comprising the three levels of a between-groups factor and the baseline, final session, and follow-up administrations providing the within-groups factor. The analysis revealed no significant main effects or interactions. Mean values for all groups indicated adequate sexual adjustment.

The Sexual Semantic Differential scores indicated the degree of positive or negative affect induced in the client by each of the seven concepts relating to either specific sexual activities or concepts with sexual arousal potential. In contrast to the Rotter scale, attitudinal changes and treatment effects were observed, as summarized in Table 1. Interaction effects were observed between treatment and time for the following sexual concepts: "sex," "nudity," "self-exploration," and "my role in sex." Means for groups at the different times at which the measures were administered appear in Table 4. With respect to the concept *sex*, post hoc comparisons indicated that whereas all groups initially had unfavorable attitudes, the two treatment groups progressively developed favorable attitudes through the 3-week follow-up, and the control condition remained at the baseline level throughout. The concept *nudity* was met with an essentially neutral response in all groups at the time of the baseline measure. The control group did not change over time, but both treatment groups exhibited favorable attitudes at the time of the 3-week fol-

Table 4

Control	.50	-4.00	-1.50	—

Note. A dash indicates that the measure was not given at this time.

low-up. The concept *self-exploration* initially yielded mildly favorable responses in all groups, with the two treatment groups subsequently improving and the control group deteriorating marginally through the 3-week follow-up. The concept *my role in sexual activity* was initially met with negative attitudes in all groups, with the two treatment groups ultimately providing evidence of favorable attitudes and the control group manifesting no change.

The concept *verbalizing sexual desires* yielded significant treatment effects and changes over time. As indicated in Table 4, the group differences can be attributed to much more favorable attitudes in the two treatment

groups than in the control group. However, the control group differed substantially from the two treatment groups at the time of the baseline measure, and it would be inappropriate to attribute differences to treatment effects. Similarly, all groups apparently improved in their evaluation of the concept over time, but this again could not be attributed to treatment because the control group improved as well. It is noteworthy that the treatment groups ultimately ended up with favorable attitudes while the control group maintained an unfavorable evaluation of the concept.

Analyses of evaluative attitudes toward the concept *orgasm* indicated that the groups

differed significantly, but there were no changes over time nor did group effects interact with time. At the time of the baseline measure, those individuals about to receive group treatment appeared to have substantially more favorable attitudes than those about to receive individual treatment or those in the control group. The two latter groups were essentially neutral with respect to their attitude toward the concept. At the time of treatment termination and the 3-week follow-up, the control group maintained the essentially neutral attitude, with the two treatment groups quite positive and not different from one another. The three groups could not be differentiated in terms of their attitudes toward the concept *male bodies* at any time during baseline, treatment, or follow-up. However, attitudes tended to become more favorable over time in all three groups.

Analyses of the 1-year follow-up data indicated that for the majority of the sexual concepts (sex, nudity, my role in sexual activity, verbalizing sexual desires, and orgasm), treatment gains observable at the time of the 3-week follow-up were maintained. No significant differences were observable between measures taken on the two occasions ($p > .05$). In addition, there were no significant differences between groups receiving individual or group treatment after 1 year. With respect to the concept *self-exploration*, there was a nonsignificant decline in attitude through the 1-year follow-up, suggesting that after this time early benefits from self-exploration had led to other more satisfying forms of experience. No change appeared in characterizations of the concept *male bodies*.

Discussion

Clients receiving group and individual graduated symbolic modeling with concurrent behavioral tasks improved significantly with respect to sexual anxiety, attitudes, and behavioral enactment, in contrast to the no-treatment control condition. Although no statistically significant differences were observed between group and individual treatment programs, clients receiving group treatment recorded less anxiety on the card sort and the anxiety dimension of the Sexual Semantic Dif-

ferential. There was also a tendency for clients receiving the group treatment to report favorably higher frequencies on the sexual behavior index. As clients were randomly assigned to the two treatment conditions, there was no reason to believe that those receiving group treatment were different from those receiving individual treatment. It is possible that components of the group treatment, such as exposure to people with similar problems, induced lower levels of anxiety and facilitated the incidence of sexual activity.

There was also a tendency toward deterioration in the control group over all indices. Behavioral frequencies generally tended to decline, and in two cases, visual sexual exposure and nonsexual sensate focus, they decreased significantly. On several other measures, there was a pattern of initial improvement with subsequent return-to-baseline incidence. There appeared to be an initial enthusiasm for involvement in what was described at the time as a "pretreatment investigation," which essentially comprised self-monitoring over the span of about 6 weeks; however, the improvement waned with time. It seems that the demand-induced increased awareness of personal sexual habits provoked anxiety and dissatisfaction to the extent that the initial favorable effects of self-monitoring (Kanfer, 1970; Kazdin, 1974) declined rapidly after the third session. It would be useful to know if clients on waiting lists for sexual dysfunction treatment all manifest this trend toward deterioration.

Because improvement was observed around the third treatment session on all measures of behavior, attitude, and anxiety, it appears that the treatment effects were consolidated simultaneously in both covert and overt behavioral systems. Including behavioral measures throughout the course of treatment not only permitted assessment of when therapeutic effects manifested themselves but indicated whether clients were complying with treatment instructions.

Results from the several measures of anxiety, the Sexual Anxiety Card Sort, the Bentler Heterosexual Behavior Hierarchy, and the Sexual Semantic Differential all indicated that both treatment programs reduced anx-

iety throughout treatment, with reduced anxiety persisting through both the 3-week and 1-year follow-up. The control subjects displayed a nonsignificant trend toward increased anxiety through the 3-week follow-up. Reductions in reported anxiety as measured by the Bentler were slightly less than those observed on the Sexual Anxiety Card Sort. As the Bentler describes more novel sexual activities than the Sexual Anxiety Card Sort, there was evidence of generalized treatment effects.

Because the Marks and Sartorius (1968) Sexual Semantic Differential was originally devised to assess sexual attitudes toward unconventional sexual activities, it is noteworthy that it was of value in the present context, thereby attesting to its flexibility and usefulness. In the initial theoretical formulation, it was expected that positive increases on the Sexual Semantic Differential would be more marked for those concepts conforming to the behavioral treatment requirements, namely, sex, self-exploration, verbalizing sexual desires, and my role in sex. The findings were partially consistent with this expectation, since treatment effects were particularly potent for the concepts *sex* and *my role in sexual activity*. Significant differences between the two treatment groups and the control group generally manifested themselves after the third treatment session. These results have implications for time-limited therapy in that treatment effects appear to consolidate themselves within the attitudinal realm fairly early during treatment programs.

In accordance with expectations, no significant changes were evidenced over the three administrations of the Rotter Sex Attitude Scale. It did not seem probable that the treatment would influence the more global attitudes measured by this scale. It was interesting to note that none of the clients scored within the maladjusted range on this scale, suggesting that personal sexual dysfunction may be entirely separate from global sexual attitudes.

The sexual behavior index disclosed treatment-induced improvement in the categories measuring the incidence of visual sexual exposure, nonsexual sensate focus, sexual sensate

focus, the number of female-initiated sexual behaviors, and the frequency of intercourse. These effects were maintained without exception through the 1-year follow-up. Although an increased incidence of orgasm tended to be a personal goal for most of the clients, it was not affected by treatment, a finding consistent with Wincze and Caird (1976). They agree with Kaplan (1974), who observed that orgasms can be conceptualized as partially independent of sexual pleasure. As such, achieving orgasm is the appropriate treatment objective of complementary, but different, therapeutic programs.

Although no statistically significant differences were observed between group and individual treatment conditions, there were tendencies for those clients receiving group treatment to engage in more visual sexual exposure, nonsexual sensate focus, and female-initiated sexual behaviors. When debriefed, the women receiving group treatment tended to express positive feelings concerning it. The major issues included a feeling of group cohesion, an increased ability to describe personal sexual experiences in public, and a sense that they wished to do well for other members of the group. Given that group treatment is far more economical, this type of program appears to have some decided advantages. The above findings indicate the viability of the group treatment as a highly desirable alternative to conventional individual treatment.

Behavioral Treatment of Problem Drinkers: A Comparative Outcome Study of Three Controlled Drinking Therapies

William R. Miller
University of New Mexico

Three therapies designed to reduce the alcohol consumption of problem drinkers were evaluated and compared. Self-referred and court-referred clients were randomly assigned to one of three treatment groups: aversive counterconditioning (AC) using self-administered electrical stimulation; behavioral self-control training (BT) including self-monitoring and instruction in functional analysis; or a controlled drinking composite (CD) including blood alcohol awareness training, discriminated aversive counterconditioning, self-monitoring, and rate-control training. All therapies were conducted by trained paraprofessionals and consisted of 10 weekly sessions. All three behavior therapies produced significant reduction in clients' weekly alcohol consumption and peak blood alcohol concentration. These gains were largely maintained over 1 year of follow-up. No significant differences among treatments were found, although AC was initially least effective in reducing alcohol consumption and producing improvement on measures of general adjustment. CD proved least cost effective, requiring four times more therapist contact than either AC or BT. A self-control manual was found to be helpful in maintaining controlled drinking.

The importance of alcohol abuse as a national health problem is apparent. Less obvious is its appropriate remedy. Adherents of the traditional disease model of alcoholism have maintained that it involves an irreversible loss of control over drinking and that the resumption of normal drinking is impossible for the alcoholic (Alcoholics Anonymous, 1955; Jellinek, 1960). The treatment of problem drinkers, dominated for the past 30 years by this viewpoint, has focused primarily on the goal of total and lifelong ab-

stinence. The general applicability of this model has been increasingly questioned, however (Armor, Polich, & Stambul, 1976; Miller & Caddy, 1977; Sobell & Sobell, 1974), and treatment methods designed to produce controlled drinking have begun to emerge (e.g., Lovibond & Caddy, 1970; Miller & Muñoz, 1976; Sobell & Sobell, 1973b).

The status of these controlled drinking therapies is uncertain at present (Nathan, 1977). A wide variety of treatment methods have been proposed for the reduction and control of drinking (Briddell & Nathan, 1975; Hamburg, 1975; Lloyd & Salzberg, 1975; P. M. Miller, 1976; Nathan, 1976). W. R. Miller (1976) has reviewed outcome research regarding seven major strategies: (a) aversive counterconditioning, (b) blood alcohol discrimination training, (c) rate-control training, (d) operant methods, (e) stimulus control procedures, (f) self-monitoring, and (g) broad-spectrum approaches. Although these techniques have been within the armamentarium of behavior therapists for some time, their *relative* efficacy in the control of drinking has not been established. To further

The present article is based on dissertation research conducted at the University of Oregon. Special appreciation is expressed to the members of my committee: Edward Lichtenstein, Robyn M. Dawes, Susan K. Gilmore, Lewis R. Goldberg, Neil McNaughton, and Lonnie Snowden.

This research was supported in part by a grant from the Distilled Spirits Council of the United States, Inc. Supplemental support was provided by the Christian Brothers and Hillcrest Vineyards and by the Department of Psychology, University of Oregon.

Requests for reprints should be sent to William R. Miller, Department of Psychology, University of New Mexico, Albuquerque, New Mexico 87131.

complicate matters, outcome studies have used varying client populations (albeit primarily inpatient alcoholics) and have, with few exceptions (e.g., Sobell & Sobell, 1973a, 1976), failed to provide long-range follow-up data.

The present study was designed to assess the relative effectiveness within an outpatient setting of three controlled drinking therapies: (a) aversive counterconditioning, (b) behavioral self-control training, and (c) direct training in rate control and blood alcohol discrimination. On the basis of the existing literature (W. R. Miller, 1976), it was predicted that all three therapies would produce significant reduction in drinking behavior over the course of treatment. Of interest was the relative effectiveness of the three methods and specifically whether the treatments would differ with regard to (a) their impact on drinking behavior, (b) their impact on measures of psychological functioning, and (c) the maintenance of whatever behavior changes they produced. Previous research has provided no basis on which to predict the relative effectiveness of the three methods.

Method

Clients

A treatment program for problem drinkers who desired "to reduce and control their drinking without stopping altogether" was announced through the local news media and mental health service agencies of Eugene, Oregon. Clients came to the program through either of two routes: self-referral or court referral.

Self-referrals. Of 45 persons voluntarily seeking treatment, 1 was excluded due to advanced liver disease. Nine others dropped out of the program prior to or during the initial assessment phase and before beginning treatment. An additional 5 clients dropped out of treatment prior to the third session, and 1 client terminated following the eighth session. The remaining 29 clients completed the 10-session treatment program.

Court referrals. Oregon law provides for the alternative sentencing to a treatment program of persons found guilty of driving while intoxicated. The sons found guilty of driving while intoxicated. The Alcohol Traffic Safety Clinic (ATSC), responsible for treating such offenders, referred selected clients to this program. During the period of intake for the present study, a total of 89 clients were processed by the ATSC.

To enter the program a court-referred client had to pass through several screening stages. Clients unwilling to sign a release permitting evaluation of

their progress ($n=10$) were excluded altogether. An additional 8 clients were incarcerated or left the community before they could be evaluated at intake. These 18 clients were thus not studied.

The ATSC staff further excluded 35 clients as inappropriate for controlled drinking. The remaining 36 clients were considered eligible for behavioral treatment. Of these, 6 refused or dropped out prior to treatment. Four began treatment but dropped out before the third session, and 1 terminated after the fourth session. All court-referred clients who dropped out of the program were referred back to ATSC for alternative therapies (primarily group and/or Antabuse). Eight clients who were otherwise eligible for behavioral treatment were randomly selected to be assigned back to ATSC as a "random" control group. A final total of 17 clients signed the release, were cleared by ATSC staff, were randomly assigned to and accepted treatment, and completed the 10 sessions.

Client Assignment Procedures

Clients were randomly assigned to one of the three treatment modes and to 1 of 10 paraprofessional therapists. All clients were informed prior to assessment and treatment of the modality to which they had been assigned. The nature of the treatment, including its potential risks and discomforts, was fully explained, and all clients read and signed a statement of informed consent for their particular treatment.

Project Staff

All treatment sessions were conducted by paraprofessional therapists trained in the behavioral procedures described below. All therapists treated clients within each of the three treatment modalities.

Therapists were recruited from among graduate and undergraduate students in psychology and allied fields and received academic credit for their participation. Eight therapists were women and two were men. By group means, the "average" therapist was 26.5 years of age, had completed 4.5 years of postsecondary education, and had had 3 years of prior experience in some form of human services. Therapists followed a detailed procedures manual for treatment sessions (Miller, Note 1) and received ongoing supervision.

All assessment procedures were administered by trained interviewers who had no contact with or responsibility for therapy. Three different teams of interviewers conducted assessment at intake and termination, at 3-month and 1-year follow-ups.

Facilities and Apparatus

A conventional interview room served as the setting for assessment and for the treatment of clients in the behavioral self-control training group. A simulated bar setting provided the environment for

the other two treatment modalities, with the therapist in the usual position of a bartender. An Omicron Intoxilyzer, Model 4011, was installed in the bar to provide feedback regarding blood alcohol concentration. Equipment for the administration of electric shock included a Lafayette Master Shocker (Model 82400) with an intensity range of 0 to 5 ma, two Lafayette Interval Timers (Model 58010), and a Lafayette Probability Generator (Model 58019). A triple-function data recorder (Lafayette Model 58004) was installed on the bar top as an in-session counter for shocks, sips, and other relevant events. A quad indicator panel (Lafayette Model 58001) was connected with the interval timers to provide signals for the proper sequencing and spacing of aversive conditioning trials.

Initial Assessment

All clients completed 4 hours of assessment prior to behavioral treatment. The first 2-hour session included a demographic questionnaire, the Minnesota Multiphasic Personality Inventory (MMPI; Hathaway & McKinley, 1943), the Michigan Alcoholism Screening Test (MAST; Selzer, 1971), Rotter's Internal-External Locus of Control (I-E) Scale (Rotter, 1966), and a Profile of Mood States (McNair, Lorr, & Droppelman, 1971). The second 2-hour session consisted of the Drinking Profile (Marlatt, 1976), a structured interview about drinking patterns and habits. Written consent was obtained from each client to contact at least two significant others for corroborative information. Whenever possible, parallel intake assessment (with the exception of the Drinking Profile) was conducted with clients who dropped out of or were excluded from the program.

Treatments

Aversive counterconditioning. The aversive counterconditioning (AC) program took place in the simulated bar setting and required 10 weekly 30-minute sessions. The client was seated at the bar and attached two plate electrodes to the ring and index fingers of his or her nondominant hand. Shock intensity, which the client could change at any time, was set at a level that he or she had rated to be painful but not intolerable. The client's one or two most frequently consumed beverages were prepared and placed on the bar.

A single trial consisted of several steps. The client was instructed to pick up the beverage, sniff it, and imagine tasting it without actually sipping. The client then pressed a foot pedal installed near the bar stool, administering a 1-sec shock. Shocks occurred only 70% of the time, being randomly scheduled by the probability generator. Upon pressing the pedal, the client put the drink back on the bar and removed his or her hand from it. The importance of timing in these steps was emphasized, and the therapist closely observed the trials. A timing system sustained a "hold" light and deactivated the

shock button for 15 sec, after which a "go" light signaled the beginning of the next trial. Between trials the client was allowed to adjust shock intensity if desired, being encouraged to increase intensity over trials. An AC session was terminated after a minimum of 40 or a maximum of 50 trials.

Clients in all treatment modalities were trained in self-monitoring and kept daily record cards of all drinks during each week of treatment. Clients in AC submitted these records to the therapist during weekly sessions, but no specific use was made of them in treatment.

Behavioral self-control training. All 10 behavioral self-control training (BT) sessions were conducted in the interview room and lasted approximately 30 minutes each. As in the other two treatment modalities, clients began self-monitoring after the first session. The record cards kept by clients included columns for recording the type and amount of each drink consumed, time of the first sip, and situational information. These cards served as the focus of BT sessions.

During each session the client reviewed the records of her or his previous week's drinking. The therapist completed basic calculations regarding alcohol consumption and blood alcohol concentration and helped the client to examine the records for stimulus antecedents of heavy drinking. Strategies for increasing future control were discussed. Suggested self-control methods encompassed three major strategies: (a) awareness and alteration of antecedents of drinking, (b) reduction of drinking rate, and (c) identification and practice of alternatives to the use of alcohol. These strategies have been outlined by Miller and Muñoz (1976).

Controlled drinking composite. The simulated bar setting served as the setting for controlled drinking (CD) sessions, which lasted between 120 and 150 minutes each. Because clients consumed alcohol during these sessions, arrangements were made for transportation to and from the clinic.

During Session 1 the client was provided with her or his most frequently consumed beverages and was instructed to drink as usual. No client was permitted during any session to consume drinks that would elevate the blood alcohol concentration above 80 mg%. Training in self-monitoring was included in this first session.

During Sessions 2-4 the client was instructed to drink in his or her normal manner and was taught to estimate the blood alcohol concentration reached after each drink by attending to both internal and external cues.¹ When the client's blood alcohol con-

¹ Sessions 1-5 had originally been intended to include blood alcohol concentration discrimination training after the manner of Lovibond and Caddy (1970). Malfunctioning of the Intoxilyzer, however, precluded its use for this purpose. When it became apparent that the malfunction could not be corrected, a procedure was substituted whereby clients were taught to estimate their own blood alcohol

centration reached 65 mg% or 30 minutes before the end of a session (whichever came first), electrodes were attached as in AC, and discriminated aversive counterconditioning (Lovibond & Caddy, 1970) was begun. During Session 2, 10 shocks were self-administered and were paired with sips of a beverage. During Sessions 3-4, 40 trials were required, pairing shocks with prepping behaviors as in AC. Conversation between therapist and client during these and subsequent sessions focused on drinking behavior, antecedents and consequences of alcohol use, alcohol education, and self-control strategies (Miller & Muñoz, 1976). Daily record cards were examined during each session to facilitate discussion of the previous week's drinking pattern.

Session 5 served as a probe session. No shocks were administered, but the client continued to record drinks, sips, and blood alcohol concentration estimates.

Sessions 6-8 focused on the reduction of alcohol consumption rate (Sobell & Sobell, 1973b). Electrodes were attached as before, but shocks were controlled by the therapist during these sessions. A list of rules similar to those used by Sobell and Sobell (1973b) was read to the client, indicating the behaviors for which a shock would be delivered. Shock intensity was set at the highest level previously tolerated by the client.

Session 9 served as a final probe, again with no shock contingency in effect. The therapist observed rule infractions but did not punish them.

Session 10 consisted of a review of the treatment process and was conducted in the interview room. A thorough functional analysis was constructed from information gained during treatment, and in vivo applications of self-control procedures were reviewed.

Termination Assessment

A portion of the final session in each treatment mode was devoted to the completion of several assessment forms, including the Profile of Mood States and ratings of treatment and therapist satisfaction. Significant others were contacted to assess current drinking behavior. Clients were asked to keep daily record cards for an additional 12 weeks, mailing them weekly. Whenever possible, parallel information was obtained from clients not receiving behavior therapies.

One half of the clients in each of the three treatment groups were randomly chosen to receive a

copy of a manual prepared as an aid in the maintenance of treatment gains (Miller & Muñoz, Note 2).

Follow-up Assessment

At 3 months following termination, clients were contacted and invited to participate in a follow-up session. A fee of \$5 was paid to each client for participation. Instruments administered at this time included a questionnaire paralleling previous measures of drinking behavior, the MMPI, Rotter's I-E scale, the Profile of Mood States, and (where appropriate) a questionnaire regarding the client's use of the manual. Significant others were again contacted for corroborative information. Driving records were obtained for all court-referred clients. Those who had not previously received a copy of the manual were given one at this time.

Whenever possible, clients not treated in the program were also interviewed and paid for their participation. To determine the appropriate time for these follow-up interviews, all nontreated clients were yoked to treated clients according to the date of their intake with the program or with the ATSC.

At 1 year following treatment termination, clients and significant others were once again interviewed by telephone and mail. Drinking behavior was assessed, and clients again completed the Profile of Mood States.

Results

Pretreatment Measures

Table 1 presents demographic data for each of the six groups studied. The groups differed on several important pretreatment measures. Contrasting self-referred with court-referred clients receiving behavioral treatment, the former reported significantly higher income and education and scored significantly higher on the MAST and on three subscales of the MMPI: Depression, Psychopathic deviate, and Rich and Davis' (1969) Revised Alcoholism Scale. Self-referred clients also reported a significantly higher rate of alcohol consumption at intake than did court-referred clients, $F(1, 40) = 19.67, p < .001$. No significant differences on pretreatment measures were found among the three behavioral treatment groups, consistent with random assignment.

Within the population of traffic violators, clients excluded by the ATSC were found to be significantly older and less educated and to have scored significantly higher on the MAST and on the three MMPI subscales mentioned above.

concentration from number of drinks consumed, body weight, and spacing of drinks. Other research has indicated this to be an equally effective procedure for blood alcohol concentration training (Huber, Karlin, & Nathan, 1976). This change necessitated the repetition of one or two sessions for five CD clients who had been using the Intoxilyzer.

Table 1
Demographic Information Regarding Client Groups

Client group	■		Age	Years of education	Annual income
	Males	Females			
Self referred					
Completed treatment	18	11	37.3	15.6	\$14,703
Refused or dropped out	11	4	32.9	14.1	\$10,034
Court referred

Random controls	6	2	41.3	13.5	\$ 9,955

Effects of Treatment on Drinking Behavior

Self-report. Clients were interviewed at intake, termination, and at 3- and 12-month follow-ups. Reported alcohol consumption at each point was converted into standard ethanol content units, with 1 standard ethanol content unit equal to .5 ounce (15 ml) of pure ethanol. Figure 1 shows the mean self-reported alcohol consumption of each treated group at each of the four assessment periods. A repeated measures analysis of variance revealed a significant decrease in drink-

ing for all groups, $F(3, 81) = 12.53, p < .001$. No significant differences among groups were observed.

Reports of significant others. Mean estimates of significant others regarding clients' drinking are presented in Figure 2. In cases in which multiple estimates were obtained, the highest estimate was used. Product-moment correlations between the reports of clients and of their significant others were calculated and yielded a puzzling pattern. At intake there was no significant relationship

Figure 1. Mean self-report of weekly alcohol consumption. (From Chapter 6 "Behavioral Self-control Training in the Treatment of Problem Drinkers" by William R. Miller. In *Behavioral Self-management*, Richard B. Stuart (Ed.). Copyright by Brunner/Mazel (1977). Reprinted by permission.)

Figure 2. Mean highest estimate from significant others of clients' weekly alcohol consumption. (From Chapter 6 "Behavioral Self-control Training in the Treatment of Problem Drinkers" by William R. Miller. In *Behavioral Self-management*, Richard B. Stuart (Ed.). Copyright by Brunner/Mazel (1977). Reprinted by permission.)

between these two data sources, $r(28) = .225$, $p > .05$. At termination there was a mild positive relationship, $r(28) = .365$, $p < .05$, whereas at the 3-month, $r(29) = .733$, $p < .001$, and 12-month follow-ups, $r(20) = .821$, $p < .001$, the reports were highly correlated. At each assessment period an approximately equal number of significant others overestimated and underestimated clients' own reports of their drinking.

Daily record cards. Alcohol consumption and weekly peak blood alcohol concentration as reported on record cards over the weeks of treatment and follow-up are presented in Figures 3 and 4, respectively. Repeated measures analyses of variance indicated significant decreases over the course of treatment both in weekly consumption, $F(8, 344) = 8.51$, $p < .001$, and in weekly peak blood alcohol concentration, $F(8, 344) = 4.52$, $p < .001$. Blood alcohol concentration peaks were estimated from body weight and consumption data (Miller & Muñoz, 1976). There were again no significant differences among treatment

modalities. In time series analyses of these data (Glass, Willson, & Gottman, 1972), all three groups showed a significant downward drift in consumption during treatment: for aversive counterconditioning, $t(17) = -3.93$, $p < .001$; for behavior training, $t(17) = -8.77$, $p < .001$; and for controlled drinking, $t(17) = -13.30$, $p < .001$, and maintained these gains, with level slopes during follow-up.

Improvement ratings. The use of improvement ratings provides an index of the status of individuals following treatment. Each client was assigned to one of six improvement categories at termination and at 3- and 12-month follow-ups.

Because a number of clients (primarily court referred) were found to be drinking very little at intake, an initial distinction was drawn between those who had been "problem drinkers" and those who had been "controlled drinkers" immediately prior to treatment. A problem drinker was defined as anyone who exceeded 20 standard ethanol content units per week or a peak blood alcohol concentra-

Figure 3. Mean weekly alcohol consumption from daily record cards during treatment and follow-up. (From Chapter 6 "Behavioral Self-control Training in the Treatment of Problem Drinkers" by William R. Miller. In *Behavioral Self-management*, Richard B. Stuart (Ed.). Copyright by Brunner/Mazel (1977). Reprinted by permission.)

Figure 4. Mean weekly peak blood alcohol concentration from daily record cards during treatment and follow-up. (From Chapter 6 "Behavioral Self-control Training in the Treatment of Problem Drinkers" by William R. Miller. In *Behavioral Self-management*, Richard B. Stuart (Ed.). Copyright by Brunner/Mazel (1977). Reprinted by permission.)

tion of 70 mg% or both, as reported by any data source. Those who, by all reports, were not exceeding these limits were classified as "controlled" at intake and were then assigned to one of two ratings. Controlled clients were rated as *improved* if they showed a noncontradicted reduction of at least 30% in alcohol consumption. ("Noncontradicted" indicates that self-report, reports of significant others, and daily record cards were all in agreement.) Clients who showed less than a 30% reduction or whose reports were contradicted by any data source were rated as showing *no change*.

Problem drinkers were assigned to one of four improvement ratings. *Considerably improved* were those clients who showed at least a 50% noncontradicted reduction in alcohol consumption or who met the controlled drinking criteria following treatment. (Abstainers fell into this category, but they are indicated separately as *abstinent*.) *Moderately improved* clients were those who showed at least a 30% noncontradicted reduction or a decrease greater than 50% that was contradicted by another data source. Clients were rated as *slightly improved* if they showed at least a 10% noncontradicted decrease or a 30%-50% reduction that was contradicted. Clients

with less than a 10% reduction or a contradicted reduction of less than 30% were rated as *not improved*.

Table 2 summarizes the number and percentage of clients assigned to each improvement rating at termination and follow-ups.

Drinker classification. Still another short-hand method for evaluating individual outcome is to determine how many reached an absolute criterion of controlled drinking. The above criteria of not exceeding 20 standard ethanol control units or 70 mg% per week defined the controlled clients, with the additional constraint that these reports could not be contradicted. Number of clients classified as problem, controlled, and nondrinkers at intake, termination, and follow-ups is reported in Table 3.

Drinking Behavior of "Control" Groups

For comparative purposes clients who were excluded from or dropped out of treatment were also evaluated. Although much less information was available for these clients and since they proved more difficult to reach for follow-up, sufficient data were obtained to assign drinker classifications at 3- and 12-month follow-ups. These are reported in Table

Table 2
Number and Percentage of Clients Assigned to Each Improvement Rating at Termination and Follow-ups

Improvement rating	At termination			At 3-month follow-up			At 1-year follow-up		
	AC	BT	CD	AC	BT	CD	AC	BT	CD

Table 3
Number of Clients in Each Treatment Group Assigned to Each Drinker Classification at Intake, Termination, and Follow-ups

Drinker classification	Assessment period											
	Intake				Termination				3 months			
	AC	BT	CD		AC	BT	CD		AC	BT	CD	
Abstinent	0	0	0		0	0	2 (13)		0	1 (6)	2 (14)	1 (6)
Controlled drinker	4 (29)	3 (18)	2 (13)		6 (43)	11 (65)	10 (67)		4 (29)	11 (65)	7 (50)	9 (53)
Problem drinker	10 (71)	14 (82)	13 (87)		8 (57)	6 (35)	3 (20)		10 (71)	5 (29)	2 (14)	3 (18)
Insufficient data	0	0	0		0	0	0		0	0	3 (21)	4 (24)

Note. Numbers in parentheses are percentages. AC = aversive counterconditioning; BT = behavioral self-control training; CD = controlled drinking composite.

4. Most notable is the high proportion of abstainers among those excluded (and thus treated by the ATSC). Correlations between self-report and significant others' reports were moderately high at both 3-month, $r(29) = .775$, $p < .001$, and 12-month, $r(37) = .480$, $p < .005$, follow-ups.

Examination of the driving records of court-referred clients at the 12-month follow-up revealed that fewer than 10% had repeated their offense of driving while intoxicated. Type of treatment received (ATSC vs. behavior therapy) had no significant effect on level of recidivism.

Effects of Treatment on Other (Nondrinking) Measures

Clients treated by the ATSC and those receiving behavior therapies showed substantial improvement on measures of personal adjustment. On the Profile of Mood States, all three behaviorally treated groups improved significantly ($p < .01$) on all six subscales over the course of treatment and follow-up. ATSC clients showed similar improvement through the 3-month follow-up, but by the 12-month follow-up they had relapsed to pretreatment levels on all subscales. Self-referred dropouts, the only untreated group, were found to be unimproved at all follow-up interviews. Behaviorally treated clients showed significant decreases on 8 of 10 clinical subscales of the MMPI, and similar improvement was found among all control groups.

Effects of a Manual on Maintenance of Controlled Drinking

Clients were randomly chosen at termination to receive or not receive a manual designed to improve maintenance of treatment gains (Miller & Muñoz, Note 2). Of the 26 who received it, 17 indicated at the 3-month follow-up that they had read all or parts of it. Alcohol consumption (from record cards) of clients who read, did not read, or did not receive the manual is shown in Figure 5.

Two-way analyses of variance were used to compare clients who read the manual with those who did not receive it. At termination,

Table 4
 Drinker Classification Within "Control" Groups at 3-Month and 12-Month Follow-ups

Classification	Court-referred						Self-referred dropouts	
	Excluded		Dropouts		Random controls			
	3 months	12 months	3 months	12 months	3 months	12 months	3 months	12 months
Abstinent	23 (66)	17 (49)	0	0	1 (13)	0	2 (13)	2 (13)
Controlled drinker	7 (20)	10 (29)	4 (36)	4 (36)	4 (50)	4 (50)	0	3 (20)
Problem drinker	1 (3)	1 (3)	3 (27)	3 (18)	0	1 (13)	7 (47)	6 (40)
Insufficient data	4 (11)	7 (20)	4 (36)	5 (45)	3 (38)	3 (38)	6 (40)	4 (27)

Note. Numbers in parentheses are percentages.

when manuals were distributed, these groups did not differ on alcohol consumption. At the 3-month follow-up, however, significant differences were found in both weekly consumption, $F(1, 16) = 4.40$, $p < .05$, and weekly peak blood alcohol concentration, $F(1, 16) = 6.21$, $p < .05$. Repeated measures analyses of variance also showed large main effects of the manual ($p < .001$) on both measures. A somewhat surprising aspect of these data is the low level of alcohol use among clients who received but did not read the manual. It appears that these were clients who had already achieved a considerable degree of control by termination, and so they "didn't bother" to read it.

Discussion

Treatment Outcome

The pattern of outcome across treatment modalities is quite consistent. All three treatment groups showed significant reduction in alcohol use. In general the AC group was least improved on all measures throughout the 3-month follow-up, but by 12 months these clients were showing gains comparable to those of the BT and CD groups. A possible explanation of this lies in the self-control manual, given to half of all clients only after the 3-month follow-up. For AC clients this manual contained new methods and informa-

Figure 5. Mean weekly alcohol consumption during follow-up of clients with and without the self-control manual. (From Chapter 6 "Behavioral Self-control Training in the Treatment of Problem Drinkers" by William R. Miller. In *Behavioral Self-management*, Richard B. Stuart (Ed.). Copyright by Brunner/Mazel (1977). Reprinted by permission.)

tion, whereas BT and CD clients had covered this material during treatment. Subsequent research (Miller, Gribskov, & Mortell, Note 3) has indicated that clients using this manual even without therapist contact can significantly reduce their drinking. The seeming reversal among AC clients between 3 and 12 months may thus be partly attributable to use of the manual.

Although no absolute differences between BT and CD were found, the pragmatics of these two treatments would argue for the use of BT, given equal effectiveness. The CD program required the use of expensive equipment: a bar, alcohol, and electric shock. BT requires none of these, is conducted in a standard therapy room, and requires less than 25% of the therapist time needed for CD. BT is also amenable to a wider variety of delivery modes including group therapy, classroom and media presentation, and self-instruction (Miller & Muñoz, 1976). In short, BT is a considerably more cost-effective and flexible approach.

The lack of difference between BT and CD modes is particularly noteworthy because the latter included all of the components of the former. CD clients received instruction in self-monitoring, rate reduction, and functional analysis of drinking behavior—the formal components of BT. In addition CD clients received discriminated aversive counterconditioning and specialized rate control training with in-session drinking and avoidance learning. These additional components apparently made little difference.

These findings underline an important point—that at least in the area of problem drinking, more extensive therapeutic programs are not necessarily more effective. It is often assumed that the addition of new components will increase the overall effectiveness of a program. This issue is a timely one with the present growing emphasis on “multimodal” and “broad spectrum” approaches (Hamburg, 1975; W. R. Miller, 1976). The utility of adjunctive procedures should be evaluated from a cost-effectiveness viewpoint (which may or may not correspond to statistical significance). Expensive additional procedures that add little to a basic treatment program

can then be discarded, and more economical and/or effective ones can be adopted.

Court-referred clients receiving behavior therapies were, because of screening procedures, less severe problem drinkers at intake than were self-referred clients. Nevertheless, court clients responded to treatment in a manner similar to that of their heavier-drinking self-referred counterparts. Both groups reduced their drinking during treatment and maintained gains during follow-up. In no case did treatment mode interact with referral source. For these reasons all clients were combined for analyses of treatment outcome.

A treatment adjunct evaluated within the present study is the self-control manual designed to improve maintenance (Miller & Muñoz, Note 2). Clients who received and read the manual showed better maintenance than did those not given the manual. This effect was a small though significant one, but the use of a self-control manual is a very economical procedure and may thus be justifiable for even small increments in improvement and maintenance (Christensen, Miller, & Muñoz, 1978).

Comparison with Control Groups

Although the present study did not include untreated controls, comparisons are possible with clients who dropped out or received alternative therapies. Of the 15 self-referred clients who refused or dropped out of treatment, only 5 were found to be abstinent or controlled at the 1-year follow-up. This group also showed no improvement on measures of personal adjustment. Clients treated by ATSC, in contrast, showed marked improvement on both drinking and psychological measures. The high frequency of abstinence among ATSC clients suggests that treatment outcome may be related to the ideology and expectations of the treating agency.

Regarding the absolute effectiveness of controlled drinking therapies, judgment must be reserved pending further research. Studies to date have not provided comparable *untreated* controls. It is possible, however, to compare the results of the present study with those of previous outcome research. Emrick (1974)

surveyed the outcome literature on alcoholism and found that the average percentage of clients becoming controlled drinkers was 5.8%, whereas an average of 33.8% became abstainers following treatment. This is the approximate pattern shown by ATSC clients, although the clinic's outcome was well above average in both categories. The pattern of outcome from behaviorally treated groups, however, differs substantially from Emrick's norms, particularly in the controlled category. The overall improvement rate of 84% at termination exceeded Emrick's norms by one standard deviation.

Finally, it is noteworthy that the present study supports the longstanding finding that outcome at a 3-month follow-up is reasonably predictive of the longer range picture with regard to drinking and personal adjustment. Of the 23 "successful" (considerably or moderately improved) cases at the 3-month follow-up for whom 12-month data were also available, 21 (91%) retained their successful status. Four of the six unsuccessful cases at 3 months were rated as successful at 1 year. With regard to drinker classification, 17 of 20 controlled drinkers at 3 months remained so at 1 year, whereas 12 of 17 problem drinkers became controlled. Of the 3 abstainers at 3 months, 1 remained so, 1 was drinking moderately, and 1 had relapsed to heavy drinking.

Conclusions

Certainly behavioral self-control training deserves further study as a treatment method for problem drinkers. A relatively economical procedure oriented toward control rather than abstinence, it offers considerable promise as an early intervention method and may also prove beneficial in the primary and secondary prevention of problem drinking (Muñoz, 1976).

The role of aversive counterconditioning in the control of drinking is more questionable. Aversion therapy, even accompanied by self-monitoring, produced the slowest and smallest initial gains of the methods studied. A counterconditioning component apparently contributed little to our multimodal (CD)

program. These findings suggest that aversive procedures can be discarded without substantially reducing effectiveness (cf. Caddy & Lovibond, 1976; Hamburg, 1975).

The present study also demonstrates the feasibility of paraprofessionals as therapeutic agents for problem drinkers. Previously inexperienced and nonalcoholic therapists effectively trained clients in self-control, producing changes comparable or superior to those of most alcohol treatment outcome studies. Apparently neither an advanced degree nor a history of alcoholism is required for effectiveness, at least with these particular treatment methods.

Further research is needed to determine the optimal combination of treatment components for the control of overdrinking. The present study supports the effectiveness of training clients in self-monitoring, rate control, functional analysis, and blood alcohol concentration discrimination, though the relative contribution of these elements is unknown. Other promising procedures include training in principles of self-reinforcement, basic education regarding alcohol and its effects, involvement of spouse or other family members in treatment, and training in alternatives to the use of alcohol (e.g., systematic desensitization, assertion training). The utility of these additional components remains to be demonstrated.

Comparison of Usual and Experimental Patients in a Psychiatric Day Center

Marsha Vannicelli and Stephen Washburn
McLean Hospital, Belmont, Massachusetts

Betty-Jane Scheff
Concord Mental Health Center
Concord, Massachusetts

Richard Longabaugh
Butler Hospital
Providence, Rhode Island

In the course of a previously reported study of inpatient and day hospitalization, 59 seriously ill female psychiatric patients were randomly assigned to an inpatient or a day hospital setting. The present study compares the 29 seriously ill patients randomly assigned to the day hospital with a control group of 34 "usual" day patients. The experimental group showed significantly more improvement from baseline to subsequent time periods in three distinct areas: global mental status, subjective distress, and family adjustment. The controls, on the other hand, spent fewer nights in the hospital, used the hospital facilities significantly less during the first 3 months, and incurred a significantly lower cost for the same period. Two measures—number of social work contacts and amount of time spent in the treatment milieu—indicate that experimentals initially required more staff effort than controls, but at later time periods the reverse was true.

A number of controlled studies, including our own (Washburn, Vannicelli, Longabaugh, & Scheff, 1976), of full versus partial hospitalization have demonstrated that patients randomized to a day hospital setting do as well as or better than those who are placed in an inpatient setting. Our study at McLean Hospital of 93 patients, 59 of whom were randomly assigned to either an inpatient or day hospital setting, indicated that on five measures the day patients fared better than those

who were placed in the inpatient program, and on the remaining nine, they did just as well as the inpatients. These findings support the feasibility of treating a large number of patients, formerly treated as inpatients, in a partial hospital setting at considerably decreased cost. What is not known is how the sicker patients, randomized to a day setting, fare compared to the population of patients normally placed there. Equally important is the emotional and material toll on the families and the partial hospital staff in treating these "unusual" day patients. Is there a trade-off somewhere or hidden cost involved in expanding day services to a population of patients who would normally be treated as inpatients? Are hospital and family resources stretched thin by placing this expanded population in the day hospital? Does this sicker population require greater amounts of community support, more psychotherapy, more extensive use of drugs, greater frequency of ancillary service visits, or more intense milieu interactions?

The purpose of this study was to try to

Research was funded in part by U.S. Public Health Service Grants RO1 MH 17464-01 and MH 17464-03A1 and by McLean Hospital Biological Research Support Grant 5 SO1 RR05484. Some additional financial assistance was received from the Fuller Foundation, Inc., Boston, Massachusetts, and the gift of Ronald and Mary Moir, for which we are grateful. We also appreciate the continuing consultation of Robert Rosenthal of Harvard University and the administrative and secretarial assistance of Ann Montague.

Requests for reprints should be sent to Marsha Vannicelli, Director of Outpatient Clinic, Appleton Treatment Center, McLean Hospital, Belmont, Massachusetts 02178.

answer some of these questions. Specifically, we were interested in (a) the relative outcome of sicker patients randomized to a partial hospital setting compared to those who would normally be placed there and (b) process differences between the two partial hospital groups in terms of (a) impact on the family, (b) involvement of the social worker, (c) quality of patient interaction with treatment milieu, and (d) ancillary therapeutic intervention.

Method

Subjects

Description of subjects, setting, recruitment procedures, and outcome measures have been detailed elsewhere (Washburn et al., 1976) and will only be briefly summarized here. Subjects were 93 middle-to upper-middle-class female patients between the ages of 16 and 72 ($M = 32.9$), admitted to McLean Hospital with a primary diagnosis of functional disorder. Of these, 59 were in the randomized group (30 inpatient controls, 29 day center experimentals) and 34 were in the day center control group.

Initial comparison of the two day center groups¹ revealed differences on two demographic and three baseline pathology variables: Proportionately more families of experimental patients (12/29) than controls (5/34) lived farther than 30 miles from the hospital, $\chi^2(1) = 4.35$, $p < .05$; the experimental sample was significantly younger ($M = 28.7$) than the control group ($M = 42.15$; $t = 4.46$, $p < .001$) and was sicker at baseline on three measures of pathology (see Table 1). The two groups did not differ with respect to religion, socioeconomic status, or number of previous hospital admissions.

Subject Recruitment and Procedure

Experimental day subjects were patients who, following an inpatient workup, would have been assigned to an inpatient setting, but they were not so suicidal, homicidal, or incapable of forming a treatment alliance as to make inpatient care an *absolute* necessity (i.e., they were patients who, for the purposes of this study, were considered to be *possibly* treatable in the day setting).

Control day subjects were (a) patients from the community who applied for admission directly to the day center and (b) patients recommended for the day center from the inpatient units. All such patients were judged to be (a) able to forego acting upon suicidal and destructive impulses, (b) able to travel to the day center, and (c) more likely to benefit from treatment in the day center than in any other setting.

Setting

McLean Hospital is a private, nonprofit psychiatric hospital. Its modern day hospital facility offers program options individualized to meet specific patient needs including individual, group, drug and activity therapies, family counseling, and milieu meetings. Program staff includes psychiatrists, social workers, psychiatric nurses, and mental health workers. Twenty-five to 40 patients attend the center daily, with a staff/patient ratio of about 1 to 4. Day center patients who, for brief periods, have difficulty managing in the community at night are housed on an unlocked night care unit.

Instruments and Outcome

Fourteen outcome measures were derived by clustering procedures: (a) Psychiatric Status Schedule—Subject Form (PSS—SF) global mental status, (b) subjective distress, (c) impulse control (Measures a–c from the PSS—SF; Spitzer, Endicott, & Cohen, 1966a), (d) Psychiatric Status Schedule—Informant Form (PSS—IF) global mental status (from PSS—IF; Spitzer, Endicott, & Cohen, 1966b), (e) Psychiatric Evaluation Form (PEF) global mental status, (f) role functioning (Measures e–f from the PEF; Spitzer, Endicott, Mesnikoff, & Cohen, 1966), (g) intrapsychic functioning (adapted from the Camarillo Dynamic Assessment Scales; May & Dixon, 1969), (h) family adjustment—subject, (i) family adjustment—informant, (j) community adjustment (Measures h–j based on Meltzoff and Blumental's, 1966, Outpatient Adjustment Rating scales), (k) burden evaluation (a project-developed graphic rating scale indicating the extent to which the patient's illness imposes a burden on the family), (l) attempted roles (informant's assessment of the number of roles the patient has tried to fill during each 6-month interval), (m) direct charges, and (n) days of attachment (calculated at 3-month intervals, the latter by summing the total days billed for at least a quarter day use of the hospital program).

Instruments and Processes

Informant Forms I and II. Based on the work of Freeman and Simmons (1963), Sainsbury and Grad (1968), and Meltzoff and Blumenthal (1966), these questionnaires were completed by the informant (a family member or friend involved in the day-to-day life of the patient) at 6-month intervals.

Informant Form I assessed the patient's effect on the family as reflected in three summary variables: (a) project assessment of burden, (b) informant subjective burden, and (c) burden imposed by the patient's core pathology.²

¹ Data from the 30 inpatient controls have been previously presented (Washburn et al., 1976).

² Details regarding composite items in these scales are available on request.

Informant Form II focused on the informant's ability to utilize hospital and community support systems, as reflected by (a) willingness to contact the hospital, (b) number of staff contacted, (c) intensity of contact (i.e., amount of contact with the most frequently contacted staff member), (d) number of people contacted outside the hospital, (e) breadth of support system (sum of variables b and d), and (f) number of services used.

The *Social Work Form*, completed monthly, provided the social worker's view of the family as reflected in (a) number of contacts about the patient, (b) necessity for social worker to initiate contacts, (c) family ability to support treatment, and (d) family tolerance for deviant behavior.

Activity logs. Each patient maintained an hour-by-hour activity log that was collected weekly by the research team. Using a random numbers table, a 1-week-long log was selected for each patient per month and averaged over the 6-month periods to obtain data on amount of time (hours) (a) in treatment milieu, (b) on hospital grounds, (c) at work and/or school, (d) in psychotherapy, and (e) in other therapies.

Social interaction. Quantity and quality of social exchange was coded at one meeting per week and was averaged over the 6-month periods to determine number of (a) healthy acts, (b) acts directed toward the patient from other patients, (c) acts toward the patient from staff, (d) acts by the patient toward other patients, (e) acts by the patient to staff, and (f) total acts by the patient.

Staff assessment of burden. During the last 9 months of the study, the day center staff rated all patients on a scale of 1 (no burden) to 7 (extreme burden). An average rank was computed monthly for each patient and was then averaged over the 9-month period.

Administration of Measures

Baseline measures of mental status and of family and community functioning were obtained prior to official acceptance into the day center. Initial measures on all other instruments were obtained within a few days after acceptance. Subsequent assessment occurred for up to 2 years.

Results

Outcome Analyses

Fourteen two-way analyses of variance with repeated measures were computed on the outcome variables examining the data over time from our two randomized groups and the day center control group. Planned-comparison *t* tests for both main effects and interactions were computed using the mean square error from the corresponding analysis of variance as the best estimate of error variance.

Main Effects

The planned comparisons for main effects were used to determine whether patients (across treatment groups) tend to get better or worse if examined at baseline and then again at later time periods. The *t* tests showed that *in general, patients improved from baseline to later periods*. These data have been reported in detail (along with the interaction effects comparing the two randomized groups) in Washburn et al. (1976).

Interaction Effects: Experimental Group Compared to the Controls

Table 1 presents the means and *t* values for measures that showed differences between patients randomized to the day center (experimental) compared with patients who normally would be treated in that setting (controls). Two-tailed tests of significance were used to compare the amount of change occurring in the experimental group between two given points in time with the amount of change occurring in the control group during the same time period.³ In addition, absolute time comparisons were made on the two groups at baseline, at 1 year, and for all analyses regarding days of attachment and direct charges.

On the *PEF global mental status*, the experimental group showed significantly more improvement from baseline to the overall posttest period and from baseline to posttest at 3, 6, and 8 months than did the controls. The control group started with significantly ($p < .01$) less psychopathology (baseline $M = 10.82$) than the experimental group (baseline $M = 14.29$) and improved very little over time, whereas the experimental group improved dramatically, becoming healthier than the controls (though not significantly so) at

³ Specific comparisons were as follows: Amount of change between baseline and Posttest 1, Posttest 2, mean of Posttests 1 and 2, the overall postrandomization period (mean of all posttests), and amount of change between Posttests 1 and 2 and Posttests 2 and 3. Where no baseline data were available, parallel comparisons were made with Posttest 1 instead of baseline.

Table 1

Significant Comparisons for Day Center Experimentals Versus Day Center Controls

Outcome measure	Experimental	Control		df
Significant difference on mean change				
Global mental status				
PEF; change from baseline to				
Overall post (through 24 mo.)	4.30 ^a	.15	2.93**	323
3rd post (Mo. 5-6)	3.47 ^a	.58	3.17**	323
6th post (Mo. 12-14)	6.31 ^a	.46	3.23**	323
8th post (Mo. 18-24)	5.24 ^a	.70	2.93**	323
PSS-SF; change from baseline to				
Overall post (through 18 mo.)	8.93 ^a	.96	2.52 ^a	136
Overall first year	9.23 ^a	2.06	2.40 ^a	136
Second 6 months	10.09	1.04	2.88**	136
Subjective distress; change from baseline to				
Overall post (through 18 mo.)	8.97 ^a	.34	2.29 ^a	136
Overall first year	9.28 ^a	1.66	2.14 ^a	136
First 6 months	10.96 ^a	.23	2.87**	136
Significant differences on absolute means				
Days of attachment (1st 3 mo.)	60.59	50.74 ^a	2.12 ^a	282
Direct charges (1st 3 mo.)	\$5,480	\$3,370 ^a	3.27***	60
Global mental status				
PSS-SF (baseline)	48.10	43.27 ^b	2.31 ^a	136
PEF (baseline)	14.29	10.82 ^b	3.70**	323
Subjective distress (1 year)	38.30 ^a	46.38	2.89**	136
Impulse control (baseline)	50.33	46.68 ^b	2.87**	136

Note. PEF = Patient Evaluation Form; PSS-SF = Psychiatric Status Schedule—Subject Form.
^a Superior outcome. ^b Less pathology.
^{*} $p < .05$. ^{**} $p < .01$. ^{***} $p < .001$.

about the 5th month. This pattern of greater improvement in the experimental group is also reflected in the data from PSS global mental status and subjective distress.

An even more pervasive pattern that appears in the PEF and is reflected in nearly all other measures is that of greater initial pathology (baseline) for the experimental group but less pathology at 1 year. In fact, on 10 out of 11⁴ measures, the experimentals appeared sicker than the controls at baseline (and significantly so on PEF impulse control and PSS-SF; see Table 1). In contrast, at 1 year the experimentals appeared better in absolute than the controls on 8 out of 11 measures (significantly so on subjective distress).

Only in terms of *number of days of attachment* and *direct costs* did the experimental group fare worse than the controls. During the first 3 months, the experimentals were attached to the hospital for significantly more days than the controls, and they incurred

⁴ The one exception appears to be a function of the peculiarities of the instrument used. The PSS-IF format is such that pathology must actually be observed to be recorded by the interviewer. Thus, for controls, who were generally living with the informant, any existing pathology is observed and recorded, whereas for experimentals, who were in the hospital and more removed from the informant, the amount of observed pathology is generally less. The Informant Form of the PSS is not an appropriate measure under these circumstances (a position with which Spitzer and Endicott now agree).

significantly higher costs. At no other time period, however, did either the cost or the number of days of attachment differ.

Process Analyses

Using the variables described under Process Measures, 27 two-way analyses of variance with repeated measures were computed to examine the data over time (baseline, 6 months, 1 year, and 18 months) for our three groups.⁵

Whereas a planned-comparison *t*-test strategy was used for the outcome analyses, the process variables were analyzed using a more traditional analysis of variance strategy, with *t*-test comparisons made on absolute scores only when *F* ratios were significant.

Main Effects: Group Differences Between Experimentals and Controls

Nights in the hospital was the only process measure that revealed significant main effects differences, $F(1, 60) = 10.03$, $p < .01$, between the two day center groups—The usual patients spent fewer nights ($M = 7.05$) in the hospital across time than the experimentals ($M = 21.98$). (The interaction effects discussed below are helpful in understanding this main effect.)

Interaction Effects: Experimental and Control Groups Compared over Time

Significant interaction effects differentiating control from experimental patients at specific time periods emerged on 8 of the 27 variables analyzed.

The meaningful⁶ significant comparisons are summarized below for each variable.

Nights in the hospital. Both experimental and control patients dropped significantly in number of nights spent in the hospital after the first 3 months ($F = 47.76$, $p < .01$). The control patients, however (who initially, and at all subsequent time periods, spent significantly fewer nights than experimentals), dropped off much less during later periods.

Intensity of contacts within the hospital. At 6 months⁷ informants involved with experimental patients had significantly more

contacts with one primary care agent than informants associated with controls, $F(6, 129) = 3.44$, $p < .01$.

Number of outside people contacted. At 18 months informants involved with experimental patients contacted significantly fewer people than informants involved with controls, $F(6, 125) = 2.78$, $p < .05$.

Social work contacts about the patient. At baseline the social worker made significantly more contacts about experimental patients than about controls, whereas at 1 year the reverse was true, $F(6, 97) = 3.35$, $p < .01$. Over time the control group did not change in terms of amount of contacts the social worker made, whereas the experimental group showed a downward trend with significant drops in number of social work contacts from baseline to each subsequent time period, and also between 6 months and each subsequent period.

Necessity for the social worker to initiate contact. The social worker felt a greater need to initiate contacts about the experimental patients than about controls at both 1 year and 18 months, $F(6, 89) = 4.33$, $p < .001$.

Both *social work contact about the patient* and *the necessity to initiate contact* show that more effort was initially expended by the social worker for experimental patients than for controls. With regard to the number of contacts a reversal later occurred—the social worker at 1 year had more contacts about the controls than about the experimentals.

Family ability to support treatment. At 18 months (but not before), families of control patients were seen by the social worker

⁵ On two measures, nights in the hospital and time spent in treatment milieu, data were examined over only three time periods (no baseline data) and for only the two day center groups.

⁶ Significant differences between the two day groups at two different times, for example, are not discussed unless in the context of other data they add meaning. Presentation of means, statistical procedures, and rationale of procedures used are detailed in a more complete manuscript, available on request.

⁷ For all analyses that follow, 6-month data reflect the amount of activity between baseline and 6 months; 12-month data reflect activity between 7 and 12 months, 18-month data reflect activity between 13 and 18 months.

as having more ability to support treatment than were families of experimentals, $F(6, 83) = 6.79, p < .01$.

Time spent in treatment milieu. Both experimental and control groups spent significantly more time in the treatment milieu during the first 6 months than at subsequent periods, $F(2, 122) = 7.19, p < .01$. Of greater interest, whereas experimentals initially (Months 1-6) spent more time in the milieu than controls, during both subsequent 6-month periods controls spent significantly more time than did experimentals.

Drug and staff burden analyses. Chi-squares examining the proportion of drug users and nonusers at 6 months and 12 months for each major drug category (major tranquilizers, minor tranquilizers, antidepressants, hypnotics, and sedatives) and t tests on staff burden ratings revealed no differences between experimentals and controls.

Discussion

Our outcome comparison of usual day patients with sicker patients experimentally treated in the day setting showed a significantly greater decrease in pathology for the experimental patients. At first glance the greater change found in experimental patients may seem less than impressive, since these sicker patients had more room to improve. These findings are more striking, however, when it is noted that on 8 out of 11 measures, the experimentals not only improved more, but at 1 year they were also healthier *in absolute* than the controls. Only in terms of direct hospital charges and number of days hospitalized did the experimentals fare worse than the controls.

These findings suggest that a sicker range of patients may be more responsive to the day setting than those normally placed there. The experimentals exhausted their outpatient treatment providers to the extent that inpatient evaluation was required. There is likely to be a lively, even turbulent, interaction with these patients that counters the apathy seen in day settings for the chronically ill.

Our process data confirm this—More effort was expended by the social worker, who, particularly at baseline, was having (and initiating) more contact about experimental patients

than about controls. At 18 months the social worker still felt more pressure to initiate contact about the experimentals although actually having fewer contacts about them than about controls. At that time the experimental families were also contacting significantly fewer people outside the hospital than were control families. By then the families of experimentals were apparently feeling less need for support (perhaps due to the dramatic improvement of their sicker member), but the social worker remained vigilant.

The initial greater exertion by the social worker for experimental patients can perhaps be best understood in terms of the flamboyant illness of these patients in the early phases of hospitalization and their greater propensity to change. This propensity to change may also contribute to the social worker's feeling of greater need to initiate contact about experimental patients and her assessment that their families were less able to support treatment. She was apparently feeling the pressure of change to a greater extent than were the families themselves.

It is important to note that experimentals not only did as well or better regarding pathology than controls—but that this occurred at no greater overall cost. It is true that experimentals, initially, are harder to handle (as indicated by hospital charges, nights spent in the hospital, days of attachment, amount of time in the treatment milieu, and pressure for social work). But after this initial period, a reversal occurred with regard to the two latter measures, with controls later requiring more attention than experimentals. In addition, in terms of 20 other important variables reflecting, (a) impact on the family, (b) interaction with the treatment milieu, and (c) need for ancillary therapeutic intervention (drugs, psychotherapy, etc.), there were no significant differences between the two groups.

The greater initial pressure imposed on the social worker by the experimental patients, greater number of days attached to the hospital, and corresponding higher charges during the first 3 months can be partially explained in terms of our study design. At the time of assignment to the day center, the experimental group had spent up to 6 weeks as inpatients and were caught in the inertia

of the hospital system. In addition, community support systems had been disrupted and needed to be remobilized—a process complicated by the fact that families of experimental patients tended to live further from the hospital than those of controls. Extensive social work effort was often needed to establish alternative living arrangements before these patients could leave the hospital.

In contrast, the community support network of the controls had been only minimally disrupted. Thus, there was less initial chaos, lower pressure on the social worker, fewer nights of hospitalization and lower hospital charges for the control group, and ultimately *less pressure toward change or improvement*. As systems theory would predict, a system is more open to change when change is already occurring; and the more acute state of the experimental patient requires immediate change. Although positive change counters chaos, it also causes further change (creating in its wake new chaos and need for additional change). The control patient, on the other hand, is part of a more static system in which fewer changes are demanded, creating less chaos and, in turn, less pressure for change (and improvement).

Other less comprehensive explanations of the experimental group's superior outcome are possible but less persuasive. The gains of experimental patients may be related to some extent to the specific effects of their initial inpatient status and their greater subsequent use of night care. Alternatively, it may be that because of their younger age and/or a possible Hawthorne effect, the experimentals received more attention than the controls and responded to this greater attention with improved performance. The social work data are consistent with the latter explanation. However, nursing staff in the day hospital, when specifically questioned, were not able to identify which patients were experimentals and which were controls, nor were there any differences in terms of staff interventions with experimental and control patients. Thus, if a Hawthorne effect were operative, it would have been an indirect function of differences in the behavior of the social worker (who worked with the significant others, rather than with the patient)—the social worker's atten-

tion affecting family members, who, as a consequence, acted differently to facilitate improvement in the patient. This explanation begins to overlap with the systems theory that we have proposed.

Perhaps the best alternative explanation for the observed differences between the two day hospital groups is that control patients were more chronically ill than experimentals. Although there was no difference between the two groups on one index of chronicity (number of prior hospitalizations), the control patients were significantly older. Their age increases the possibility that they may have been more chronically ill—perhaps due, at least in part, to years of insufficient systems demand for change.

Only further research can sort out the extent to which our results can be accounted for by these overlapping explanations. However, whatever the explanation, our data suggest that expansion of day services to include patients who have normally been treated as inpatients may require more initial effort, but this effort pays off.

Comparative Effectiveness of Day Hospital and Inpatient Psychiatric Treatment

W. E. Penk and H. L. Charles

Veterans Administration Hospital, Dallas, Texas

T. A. Van Hoose

Southern Methodist University, Dallas

The question, "Are treatment effects of partial hospitalization comparable to effects of full-time hospitalization?" was studied by means of a pretreatment-posttreatment control group design. Ratings of home and community adjustment were obtained from community informants (relatives or close friends) for 24 day hospital clients (partial hospitalization condition) matched with 24 inpatient clients (full-time hospitalization condition), as well as from an unmatched sample of 79 consecutive inpatient admissions. All groups evidenced improvement 2 months after treatment started, particularly on measures of symptom reduction. Although patterns of improvement were comparable for both settings in univariate data analyses, multiple discriminant function analysis indicated that the day hospital sample evidenced greater gains in attentiveness and in employment. Gains favoring the day hospital sample were more striking for the unmatched three-group comparison than for the matched two-group comparison. The findings indicate that partial hospitalization is an attractive alternative to inpatient psychiatric hospitalization; further, differences in subject characteristics are influential in studies of treatment outcome.

Efforts to evaluate different systems for delivering mental health services are increasing (e.g., Struening & Guttentag, 1975). Program evaluation methodology, however, is still developing: Investigators continue to question which measures reliably and validly assess treatment outcome, which perspectives in treatment outcome are preferred, and whether

assessment should concern general treatment effects or an individual's attainment of specific goals (e.g., Schulberg, Sheldon, & Baker, 1969).

Despite uncertainties, program evaluation based on multiple measures obtained from another person significant to the client in treatment has emerged as a reliable and valid source of data (e.g., Ellsworth, 1975). Systematic observations of home and community adjustment, rated by a person close to the client or so-called "community informant," seem to provide an acceptable and important perspective for inferences about treatment effects.

The purpose of the present study was to compare, from the community informant's perspective, differential effectiveness of two approaches in psychiatric treatment: day hospital (or part-time) treatment versus inpatient (or full-time) psychiatric treatment. Although day hospital and inpatient treatment approaches share in common many program-

This research was supported by the Medical Research Service of the Veterans Administration. Preliminary findings were reported at the annual meeting of the American Psychological Association, Honolulu, Hawaii, September 1972. The authors are indebted to the former Hospital Director, E. P. Whitaker, Veterans Administration Hospital, Dallas, Texas, who gave assistance in data collection, and to Isham Kimbell, Chief, Psychiatry Service, Veterans Administration Hospital, Dallas, Texas, who provided diagnostic and psychiatric ratings for inpatient psychiatry admissions.

matic features (such as individual and group therapy), the two approaches differ in amount of time a client spends at the respective treatment locale—8 hours a day for the day hospital setting versus 24 hours a day for the inpatient psychiatric setting. Supposedly, less time spent in the day hospital disrupts the client's home and community involvement less, whereas more time spent in an inpatient unit, so the notion goes, fosters overdependency on the institution and interferes with home and community social ties (e.g., Jones, 1953).

Clinical impressions have supported the view that day hospitalization is an effective treatment alternative to inpatient hospitalization (e.g., Chasin, 1967). Exploratory experimental efforts have indicated that favorable treatment outcome is associated with the part-time system of mental health services (e.g., Guy, Gross, Hogarty, & Dennis, 1969); specifically, day hospitalization seems to disrupt the client's employment status less (cf. Herz, Endicott, Spitzer, & Mesnikoff, 1971). Such findings were observed, however, in studies flawed by methodological shortcomings, such as absence of control groups or comparisons of samples differing in subject characteristics notably influential of treatment outcome. As program evaluation methods have improved, investigators have become less certain that differences in treatment systems contribute to differences in treatment outcome (e.g., Ellsworth, Note 1; Ellsworth, Finnell, & Leuthold, Note 2).

The present study compared day hospital and inpatient differential treatment effects under conditions in which subject characteristics were controlled. The experimental strategy comprised both a "fixed scale" and a "fixed time" approach—fixed scale in the sense that all subjects were compared for outcome differences on the same set of multiple measures of psychosocial functioning derived from ratings by community informants assessing clients' home and community adjustment before and after treatment, and fixed time in the sense that pretreatment and posttreatment time duration did not vary from subject to subject.

Method

Experimental Strategy

A modified form of the pretreatment-posttreatment control group design served as the experimental strategy (cf. Campbell, 1969, Design 4). Day hospital clients comprised the experimental group; inpatient clients, matched for relevant demographic characteristics with day hospital clients, served as the primary control group. The matched inpatient sample was selected from 22% of total inpatient admissions during the 2-month time period of the study (in 1972). A second control group sample was drawn from the remaining number (78%) of consecutive admissions. This second "unmatched" inpatient control group consisted of those inpatients not matched with the day hospital subjects but admitted to the inpatient unit during the time of the study. The unmatched inpatient sample furnished an additional perspective for analyzing sample comparability of the matched day hospital-inpatient cohorts, particularly whether constraints had been introduced by matching in sampling on the "external generalizability" (cf. Campbell, 1969) of the findings.

Subject Selection

Matching of day hospital and inpatient samples followed a cohortlike pairing procedure. A board-certified psychiatrist, attending intake staffing conferences in both settings, paired those inpatient admissions who seemed similar to day hospital admissions in age, type, and severity of personal problems and comparable resources in coping with conflicts. The process of subject pairing seemed free of subjective and institutional biases, particularly since there were no fixed criteria for day hospital admission at the time data were collected. Although the samples appear to be representative of clients in inpatient and outpatient psychiatric units in general medical and surgical Veterans Administration hospitals, several categories of subjects (or 9% of admissions during the study period) did not participate, that is, the physically infirm with psychological disorders, those with severe chronic brain disorders, and those who were acutely suicidal or homicidal.

Additional steps were followed to insure comparability of matched day hospital and inpatient samples on background characteristics and current levels of intelligence and personality functioning. Each of the matched subjects was rated by his attending psychiatrist on the Brief Psychiatric Rating Scale (BPRS; Overall & Gorham, 1962); samples did not differ significantly on the 18 scales. Matched subjects did not differ on measures obtained from a brief psychological screening battery (which included a biographical inventory, the Shipley Institute of Living Scale, Shipley, 1940, and several standardized measures of personality variables). Matched subjects did not differ on informants' reports about

home and community resources and background (e.g., income, living arrangements, treatment outcome expectancy, etc.).¹

The matched samples averaged 32 years of age, completed approximately 11½ years of education, and scored within the average range of intelligence (Wechsler Adult Intelligence Scale equivalency scores = 108). Nearly two thirds of both samples were married; half were employed. Forty-eight percent of both samples were diagnosed as schizophrenic, and average length of program participation was about 33 days.

Program Evaluation Instrument

The Personal Adjustment and Role Skills scale (PARS, Ellsworth, 1975) served as the measure of treatment outcome. The PARS consists of 57 items and is scored for eight factor-analytically derived measures of home and community adjustment. Reliability and validity of PARS scales are well established; manuals are available, and scale definition and development have been detailed elsewhere (Ellsworth, 1975; Ellsworth, Foster, Childers, Arthur, & Kroeker, 1968). Seven scales were analyzed in the present study: (a) Interpersonal Interaction, which registers reactions to social interaction; (b) Agitation-Depression, which measures feelings of pessimism; (c) Anxiety, which assesses tenseness; (d) Confusion, which evaluates attentiveness and efficiency in mental concentration; (e) Alcohol and/or nonprescribed drug use, which estimates moderation in alcohol or drug use; (f) Social Activity, which reflects the number of social contacts (e.g., attending movies or visiting friends); and (g) Employment, which gauges amount and participation in productive, gainful employment. An eighth scale, Parent-Child Interaction, was omitted from analysis, since it did not apply to all subjects. The first five scales are described as measures of symptoms; Social Activity and Employment are regarded as measures of instrumental role activity.

Procedure

Veterans were asked shortly after admission to participate in a study evaluating effectiveness of their treatment. Each man who volunteered (indicated by signing a consent form after reading details of the research plan and the PARS) nominated a relative (or close friend) who could be contacted by mail for information about home and community adjustment before treatment ("pretreatment" phase) and then again 2 months after treatment started (posttreatment phase). Thirty-seven pairs of matched day hospital and matched inpatient admissions agreed to participate; 35 day hospital and 37 inpatient informants returned scorable pretreatment scales (pre-PARS), and 24 day hospital and 24 inpatient informants returned posttreatment scales (post-PARS) 2 months later. The matched samples, then, consisted of 24 day hospital-inpatient pairs for whom

both pre- and post-PARS, BPRS, and group psychological screening battery scores were available. (No significant differences were found for pre-PARS scores when comparing the group returning pre-PARS only with the group returning both pre- and post-PARS.)

Informants were sought also for the unmatched inpatient sample. One hundred thirty inpatient admissions (or 95% of the unmatched inpatient sample) agreed to participate: 108 informants returned scorable pre-PARS and 79 mailed back both pre- and post-PARS scales. These 84% pre-PARS and 62% post-PARS return rates were higher than the expected rate of return (cf. Ellsworth, 1975; Fontana & Dowds, 1975).

Treatment Settings

Programmatic activity was similar in both treatment settings. The main difference was time spent in the unit—8 hours a day for the day hospital versus 24 hours a day for the inpatient unit.²

The general medical and surgical hospital that contains both units is located in a large Southwestern metropolitan complex. The day hospital was situated in a single-purpose unit located on the hospital grounds but separate from the main complex. A daily structured program of individual and group therapy was offered along with regularly scheduled periods for occupational and recreational therapy. Staff ratio was 1:4; five staff members (psychiatrist, nurse, social worker, psychologist, and secretary) had an average daily patient load of 20.

The inpatient unit, housed in the main general medical and surgical complex, consisted of four wards and four treatment teams. Staff ratio was 1:4, with five staff positions (psychiatrist, nurse, nursing aide, with halftime social worker, psychologist, occupational and recreational therapists) responsible for approximately 20 patients. The inpatient treatment program consisted of scheduled activities similar to those found in the day hospital, including ward self-government meetings.

Research Questions

Three questions were addressed from the stance of the pretreatment-posttreatment control group design. First, Do post-PARS ratings differ from pre-PARS ratings for the matched day hospital and inpatient samples combined? In other words, Was there evidence of improvement following 2 months of

¹ Supplementary tables are available containing descriptive and inferential statistics for psychiatrists' ratings, psychological test scores, and informants' ratings of home information.

² A supplementary table describing type and amount of time spent in treatment activity, diagnosis, and length of stay is available from the first author.

treatment? Second, does the pattern of improvement (or pre- and post-PARS differences) vary between the matched day hospital and inpatient samples? In other words, Does treatment outcome differ as a function of treatment setting? Third, Do findings for the matched day hospital and inpatient samples hold when compared with pre- and post-PARS differences for the unmatched inpatient sample? In other words, Do the findings generalize?

Results

Patterns of Improvement for Matched Groups Combined

Matched day hospital and inpatient samples combined evidenced significant gains in correlated-means *t*-test comparisons of four of the seven PARS scores. For the measures of symptoms but not instrumental role skills (Table 1), increased Calm-contentedness, $t(47) = 5.44, p < .001$; for increased Attentiveness, $t(47) = 2.18, p < .03$; for lessened Anxiety, $t(47) = 6.76, p < .001$; and for moderation in Alcohol Abuse, $t(47) = 4.37, p < .001$.

Treatment Effects for Separate Programs

Day hospital. The day hospital sample, considered separately by correlated-means *t* tests (Table 2), evidenced increased Calm-contentedness, $t(23) = 4.51, p < .001$; increased Attentiveness, $t(23) = 3.03, p < .001$; lessened Anxiety, $t(23) = 6.18, p < .001$; and increased moderation in Alcohol Abuse, $t(23) = 2.02, p < .05$.

Matched inpatient sample. The matched inpatient sample, comparing pretreatment and posttreatment PARS scale differences by correlated-means *t* tests, evidenced similar changes: increased Calm-contentedness, $t(23) = 3.30, p < .003$; lessened Anxiety, $t(23) = 3.65, p < .001$; and increased moderation in Alcohol Abuse, $t(23) = 4.22, p < .001$. The inpatient sample gain for Attentiveness, unlike the day hospital scores, did not reach an acceptable level of significance ($\alpha = .05$).

Unmatched inpatient sample. The unmatched inpatient sample evidenced less magnitude in change than either of the two matched groups; moreover, the unmatched inpatient group sustained a significant loss in

Table 1
Pre- and Post-PARS Normative Scores for Day Hospital and Inpatient Samples Combined

Variable	Pre-PARS		Post-PARS	
	<i>M</i>	<i>SD</i>	<i>M</i>	<i>SD</i>
Interpersonal involvement	47.77	8.41	50.17	8.20
Calm-contentedness	39.50	10.42	47.29	11.27
Attentiveness	38.54	12.25	43.06	11.56
Anxiety	38.31	7.94	47.52	9.11
Alcohol abuse	42.42	13.21	49.15	9.42
Social activity	43.06	7.95	42.42	7.76
Employment	29.35	15.68	29.92	16.28

Note. PARS = Personal Adjustment and Role Skills scale. $n = 48$ for both pre-PARS and post-PARS.

Employment (Table 2). Correlated-means *t*-test differences were significant for increased Interpersonal Interaction, $t(78) = 2.26, p < .03$; increased Calm-contentedness, $t(78) = 5.22, p < .001$; increased Attentiveness, $t(78) = 3.51, p < .001$; lessened Anxiety, $t(78) = 5.17, p < .001$; moderation in Alcohol Abuse, $t(78) = 3.99, p < .001$; and decline in Employment, $t(78) = 2.78, p < .007$.

Differential Comparisons of Matched Samples

The matched day hospital and inpatient samples were comparable on six of seven pre-PARS scales, differing only in greater moderation in Alcohol Abuse for the day hospital sample, independent-means $t(46) = 2.38, p < .03$. Post-PARS independent-means *t*-test comparisons, however, resulted in a larger separation between the two matched groups. The day hospital sample was higher in Calm-contentedness, $t(46) = 1.78, p < .08$; Social Activity, $t(46) = 2.93, p < .005$; and Employment, $t(46) = 2.57, p < .03$. The two matched groups did not differ significantly in gain score comparisons (i.e., when comparing separately the difference between each pre- and post-PARS scale score).³

³ Simple difference (or gain) scores were analyzed following recommendations of Fontana and Dowds (1975).

^a *n* = 24.

^b *n* = 79.

^c Gain scores include both negative and positive numbers; accordingly, standard deviation values may be larger than mean values in some instances.

Both groups achieved significant gains. Improvement, however, does not vary widely as a function of differences in health delivery system. Three findings in the univariate statistical analysis suggest greater, albeit mild, advantages for the day hospital experience: (a) the significant increase in Attentiveness for the day hospital sample when differences were analyzed separately for each setting, (b) greater gains in all PARS scores considered collectively but not separately, and (c) higher post-PARS Social Activity and Employment for the day hospital sample after

nonsignificant pre-PARS (except for Alcohol Abuse). Such trends, discernible by univariate analysis, reinforced a need for multivariate analysis. Further analysis was justified a posteriori by finding significant intercorrelations among the PARS scales.⁴ Multiple discriminant analyses (Klecka, 1975) were performed separately for pre-PARS, post-PARS, and gain scores (a) in two-group comparisons be-

⁴ A supplementary table of pre- and post-PARS scale intercorrelations is available on request.

tween matched day hospital and inpatient samples and (b) in a three-group comparison among matched inpatient and day hospital samples and the unmatched inpatient group.

Multivariate Analysis of the Two Matched Samples

The matched samples did not differ for either pre-PARS or gain scores, whereas significant differences were found for post-PARS scores. The day hospital sample scored higher on Social Activity, univariate $F(1, 46) = 8.56, p < .001$, and for Employment, $F(1, 46) = 6.60, p < .001$. One discriminant function significantly separates the two matched groups, eigenvalue = .612; canonical correlation = .616; Wilk's $\Lambda = .620$; $\chi^2(6) = 21.01, p < .002$. Less depression (reverse scoring of Calm-contentedness) and more Social Activity and Employment differentiates the day hospital sample from the inpatient group. (See Table 3 for standardized discriminant coefficients and group centroids.)

Multivariate Analysis of the Three Matched and Unmatched Samples

Results indicate a more favorable outcome for the day hospital sample when multivariate analysis was performed in a three-group comparison, that is, matched inpatient and day hospital with unmatched inpatient sample. First, the three groups did not differ in univariate and multivariate comparisons on pre-

PARS scores. Second, significant differences occurred in both univariate and multivariate post-PARS scale comparisons; the day hospital sample obtained significantly higher post-PARS Employment scores, $F(2, 127) = 6.58, p < .001$, and Social Activity scores, $F(2, 127) = 3.21, p < .05$. Multivariate analysis yielded two significant discriminant functions (see Table 3 for coefficients and group centroids): The first obtained an eigenvalue of .218; canonical correlation = .423; Wilk's $\Lambda = .749$; $\chi^2(6) = 11.47, p < .05$. The first discriminant function varied along a continuum from disruption in thinking (interferences in Attentiveness) to Employment and lessened Anxiety; the second function varied from depression and social inactivity to lessened Anxiety. Post-PARS group differences were characterized by rated increases in Employment and Attentiveness (with which the day hospital sample aligned) and decreases in Anxiety (with which the inpatient sample aligned).

The three groups differed significantly on PARS gain scores. The day hospital sample evidenced a greater decrease in Anxiety, univariate $F(2, 127) = 3.29, p < .05$, and a greater increase in Employment, $F(2, 127) = 3.48, p < .05$. The discriminant function for gain scores, although nonsignificant ($p < .06$), was comparable to the first discriminant function for post-PARS scores; that is, the day hospital sample was higher in posttreatment Employment and lower in posttreatment Anxiety.

Table 3
Discriminant Function Coefficients

Variable	Two-group comparison coefficient	Three-group comparison	
		First coefficient	Second coefficient
Interpersonal involvement	.431	-.051	.674
Calm-contentedness	-.862	1.43	-.882
Attentiveness	.834	-.972	-.181
Anxiety (lessened)	.084	.722	1.001
Alcohol abuse (moderation)	-.252	-.091	-.553
Social activity	-.760	.334	-.614
Employment	-.787	.882	-.034
Group centroid			
Matched day hospital	-.766	.958	-.101
Matched inpatient	.766	-.068	-.643
Unmatched inpatient		-.261	-.158

Discussion

Informants regarded clients in both settings as improving in home and community adjustment. Such improvement was registered more in measures of symptom reduction than in measures of instrumental role skills (cf. Ellsworth, 1975; Fontana & Dowds, 1975).

Generality of the findings was limited by the comparatively narrow pretreatment and posttreatment time interval. Previous research suggests, however, that most variance is accounted for by patients' level of adjustment 1 month after discharge (Ellsworth & Schoonover, Note 3). The present findings thus may reflect a persisting effect of treatment outcome.

The present strategy of using two control groups in comparing differential treatment effectiveness indicated that the matching procedure did not isolate a sample that was unrepresentative of those seeking treatment; the results may be extended to the treatment setting in general. Other questions were raised, however, by this research tactic. Why were group differences more pronounced for the unmatched group comparison than for the "matched" group comparison? Obviously, outcome gains were maximized in the three-group comparison but minimized in the two-group comparison. Although it was not possible to identify factors associated with this phenomenon, the observation that degree of improvement varies as a function of differences in background characteristics of samples demonstrated the importance of describing samples in detail (cf. Campbell, 1969).⁵

Although treatment gains were achieved by both the day hospital and the inpatient samples, the evidence suggested, nevertheless, a more favorable outcome under the day hospital condition. The trend favoring the day hospital experience was barely discernible in the univariate analysis but was delineated in the multivariate analysis by the emerging pattern of gains in employment and social activity unique for day hospital clients. The result was not unanimous, for gain score differences (barely) failed to show a similar trend. Finding significantly less disruption in employment for the day hospital sample is consonant

with findings in earlier studies (e.g., Herz et al., 1971; Ellsworth et al., Note 2).

If one accepts a more prudent interpretation—that day hospital treatment is at least an acceptable alternative, but not necessarily a better alternative, to inpatient treatment for most clients seeking inpatient or outpatient treatment—then the question about which modality is the treatment of choice could be debated from the standpoint of other considerations. One such consideration is treatment "costs."

The day hospital approach recommends itself further based on its comparatively lower cost. Direct costs for each day hospital client averaged \$33.26 per day (or \$39.02 for indirect costs) compared with \$43.16 a day for each inpatient client (or \$73.49 including indirect costs).⁶ Cost parameters such as salaries, housing, equipment, and so on, do not mean necessarily that the "costs" of treatment have been estimated in their entirety, however. "Cost" of treatment, like the cost of living, is a multidimensional construct whose amount is determined not only by the assessment of material outlay but also by weighing the extent to which family, friends, and client are taxed in the process of coping with emotional distress. The use of community informants when evaluating outcome taps a significant dimension in determining cost. The evidence supports the notion that at least from the perspective of the community informant, day hospitalization is an important treatment alternative for many people.

⁵ Diagnosis (e.g., schizophrenic vs. nonschizophrenic) did not emerge as a significant outcome variable (cf. Erickson, 1976).

⁶ The authors wish to thank John Molnar-Subajda, Management Analyst, Veterans Administration Hospital, Dallas, Texas, for computing average daily costs for day hospital and inpatient psychiatry units.

Test Anxiety and the Passage of Time

Irwin G. Sarason and Rick Stoops
University of Washington

Three experiments were performed dealing with the relationship of test anxiety and achievement-oriented instructions to time perception. After being given either achievement-orienting or neutral instructions, subjects waited for an undesignated period of time and then performed an intellectual task. The dependent measures were subjects' estimates of the duration of the waiting and performance periods and their scores on the assigned task. High-test-anxious subjects' time estimates were significantly greater than the estimates of the other subjects, and their performance was at a relatively low level. Evidence is presented supporting the hypothesis that highly anxious persons under stress experience cognitive interference and preoccupation that makes time pass slowly and results in poor performance. The implications of the findings are discussed particularly in terms of the need for training programs capable of fostering improved cognitive skills requiring self-control.

Although the generalization that time is precious holds for many situations, it does not always seem to have validity. There are situations in which time drags and one wishes it were possible to speed up the clock. For the football team behind 30-0, time moves slowly, whereas for the team on the way to victory, time flies and its players desire more time to win "big." Similar differences in subjective time estimates seem to hold for many types of situations and events, a critical factor being the character of the particular situation. For example, waiting for what may be bad news about a loved one who is in the hospital can be excruciating, and there is evidence that time passes very slowly for depressives (Bech, 1975).

Although the literature on time estimation is sizable, much of the work done has focused on time estimation as a function of either personality characteristics (such as anxiety) or experimental conditions (see Meade, 1966;

Siegmán, 1962). In analyzing subjective judgments of time duration, it seems logical to consider simultaneously two variables: the situation and the characteristics (hopes, fears, etc.) that a person brings to the situation (Buchwald & Blatt, 1974; Sarason, Smith, & Diener, 1975). The present article reports the results of three experiments devised from this perspective. An important feature of the experiments is the inclusion of two types of data—time estimations and performance.

In these experiments subjects were told that they would be administered a test of intelligence but that there would first be a waiting period. (There were also control groups not given the achievement-orienting communication.) How does time pass while awaiting the evaluation? Obviously the way in which the intellectual evaluation is construed has a bearing on the answer to this question. Many psychological instruments reflect aspects of the construing process and the meanings that individuals attach to particular types of situations. Scales dealing with well-defined situations, such as those designed to tap test and speech anxiety, can be viewed as measuring cognitive activity and worrying, which is stimulated by a specific event or demand (such as having to take a test or make a speech).

This research was supported in part by Office of Naval Research Contract N00014-75-C-0905 NR 170-804. We are indebted to John Granach and Hans F. N. Crombag for their assistance.

Requests for reprints should be sent to Irwin G. Sarason, Department of Psychology, University of Washington, Seattle, Washington 98195.

The personality measure used in the three experiments was the Test Anxiety Scale (TAS; Sarason, 1972). High scorers on this measure have been shown to perform more poorly than others on difficult, complex tasks administered under achievement-orienting conditions that emphasize the evaluation of one's performance (Sarason, 1975). Test anxiety can be interpreted as a form of self-preoccupation—characterized by self-awareness, self-doubt, and self-depreciation—that influences overt behavior and psychological reactivity. Other types of anxiety may be similarly interpreted. The self-preoccupying thoughts of the highly anxious individual interfere with adaptation at several points in the course of information processing. They narrow or otherwise influence the attentional focus on environmental cues; distort encoding, transformation, and planning strategies; and influence responses that may be selected to cope with challenges confronting the individual.

Available evidence suggests that the relatively poor performance of highly test-anxious persons under achievement-orienting conditions is not due to low intelligence but rather to the cognitive interference of a personalized, self-centered approach to evaluational situations. The expectations of a highly anxious person seem to be different from those of others (Doris & Sarason, 1955). When this person performs poorly, it may not be due merely to cognitive interference and self-preoccupation during the test. It may also be related to the time spent *anticipating* the test with dread. These personalized anticipations contribute to inefficient, ineffective preparation for the test.

The experiments reported here were aimed at providing information about the way in which persons differing in anxiety fill time. It was predicted that in the presence of achievement-orienting cues, time would pass more slowly for high-anxiety scorers than for middle- and low-anxiety scorers. When these cues are not present, there should not be a significant gap in estimates of time duration among groups differing with regard to test anxiety. Furthermore, the effects of an achievement orientation should be as noticeable while the individual is waiting to perform

as during performance itself. The first two experiments deal with these hypotheses and differed in the length of the waiting period preceding performance. In the third experiment, the performance period was greatly lengthened, and a specially prepared postexperimental questionnaire was administered in an attempt to clarify the relationships among achievement orientation, test anxiety, and cognitive interference. It was expected that highly anxious persons who are underachievers would describe themselves as having more task-irrelevant thoughts than would persons with middle and low anxiety scores.

Experiment 1

Method

Subjects. The subjects were 48 male and 48 female students from introductory psychology classes at the University of Washington. All subjects were approximately 18–19 years of age. Prior to and independent of the experiment, 550 students had been administered the TAS (Sarason, 1972). The subjects were drawn from the top and bottom 15% of the distribution of TAS scores and from a group in the middle of the distribution. The subjects in the high TAS group had scores of 26 and above; subjects in the low TAS group had scores of 9 and below. The middle TAS group had scores between these cutoff points. Subjects' assignments to experimental conditions were random within the requirements of the experimental design. (This method of assignment to conditions was followed in all three experiments.)

Procedure. After being escorted into the experimental room, subjects were asked to put their watches out of sight until the end of the session because, they were told, a watch might be a distracting stimulus during the experiment. Each subject was given the task of writing a short self-description and a description of one other person. They were allotted 3.5 minutes for each description. The subjects, who were run individually, were then given either achievement-orienting or neutral instructions. The achievement-orienting instructions were given as follows:

The test you are about to take is part of a widely used intelligence test. This is the most crucial part of this study, since it will be used to give me a measure of your intelligence. I have to get the materials. I'll be back shortly.

The experimenter then left the room and shut the door. The experimenter returned 2 minutes later with the test materials and asked the subject to write down (in minutes and seconds) the length of time that he or she had been sitting alone. The experimenter then continued with the following:

As I said, the test you are about to take is part of an intelligence test. This test has been found to

predict such things as course grades, success in later life, and, to some extent, the kind of personality you possess. Of course, your own intelligence will primarily determine whether you do well or poorly on the test. At a later date you will have an opportunity to compare your IQ score with those of the other people in this study. You will then be able to determine how your abilities and capacities compare with other people like you.

The subject was then given a difficult version of the digit symbol task (variations of the letter *L*) with the following instructions: "The purpose of this task is to put the symbols in the numbered boxes as prescribed by the code at the top of the page. Try the three examples." The materials were an adaptation of those used by Sarason and Palola (1960). The subject then worked for 3.5 minutes on the digit symbol task and was asked to write down (in minutes and seconds) the length of time that he or she had been working on the test. The subject was then debriefed and excused.

The neutral instructions were as follows: "I have to get the materials we need. I'll be back shortly." The experimenter then left, returned in 2 minutes, and asked the subject to write down (in minutes and seconds) the length of time that the subject thought the experimenter had been gone. The experimenter then gave instructions on how to perform the digit symbol task. The subject worked for 3.5 minutes, after which he or she was asked to write down (in minutes and seconds) the amount of time that he or she had worked on the task. The subject was then debriefed and excused.

Results

A $3 \times 2 \times 2$ analysis of variance (encompassing test anxiety, sex, and conditions) of subjects' time estimates while waiting to do the digit symbol task failed to yield statistically significant results. However, the results for the Test Anxiety \times Conditions interaction were in the expected direction, $F(2, 84) = 3.73$, $.05 < p < .10$. The mean waiting time estimate of the high TAS subjects in the experimental group was 156.8 sec, whereas the mean for the high TAS control group was 127.7 sec. On the other hand, the middle and low TAS control and experimental group means were in the opposite direction. When the time estimates were grouped into intervals defined by overestimates, underestimates, or exact estimates of the actual time period and a chi-square analysis was performed, anxiety and conditions were found to interact significantly, $\chi^2(10) = 19.32$, $p < .05$. High TAS subjects overestimated the interval during which they believed they were waiting to take

a test to a greater extent than those in the high TAS control group. More low and middle TAS subjects overestimated the interval during which they believed they were waiting to perform on a neutral task than did low TAS subjects, who believed that they were waiting to take a test. The results for time estimates of the period in which subjects performed were in the same direction as for the waiting period but were not statistically significant.

An analysis of variance of the digit symbol performance scores yielded one significant result, that for the test anxiety main effect, $F(2, 84) = 4.07$, $p < .05$. The low TAS mean (92.8) was higher than the middle (82.2) and high (81.5) means. There were no significant sex differences in either Experiment 1 or 2.

Experiment 2

Although in several respects the results of Experiment 1 were consistent with expectations, they tended to be weak and in some instances inconsistent, for example, the fact that the middle TAS group's performance scores more closely resembled those of the high TAS group than those of the low TAS group. In the hope of uncovering more decisive relationships, a second, related experiment was performed. Two changes pertained to the temporal variable. Because the 2-minute waiting period in Experiment 1 might not have been long enough to allow for significant effects of the test anxiety and experimental variables to show up, the waiting period in Experiment 2 was lengthened to 4 minutes. In addition, subjects performed the digit symbol task for 4 instead of 3.5 minutes.

Another change in Experiment 2 was the task on which subjects worked prior to performing the digit symbol task. Instead of writing a short self-description and a description of one other person, subjects performed for 7 minutes on an anagrams task. This type of concept-formation task was deemed somewhat more consistent than the writing task, since the experimental emphasis was on the evaluation of intellectual performance. For the achievement-oriented group, the anagrams were so difficult that it was certain that no subject could complete the task in the allotted time. For the control group, the anagrams

were relatively easy, and all subjects successfully completed the task. The changes made in the preliminary task (particularly its difficulty level and time pressure) were designed to heighten stress on the evaluation of performance among subjects in the achievement-orientation group.

Method

Subjects. The subjects were 120 undergraduates at the University of Washington. The 60 males and 60 females were divided into groups on the basis of their scores on the TAS using the same cutoff points as were used in Experiment 1.

Procedure. The experiment followed a $3 \times 2 \times 2$ analysis of variance design. The variables were (a) TAS—high, middle, and low scorers; (b) conditions—achievement-orienting and neutral control; and (c) sex—male and female subjects.

This experiment used the procedures of Experiment 1 except for the following changes: (a) Before performing the digit symbol task, subjects worked on anagrams (easy ones for those in the control group, difficult ones for the experimental or achievement-orientation group), and (b) the waiting period and time for performance on the digit symbol test were 4 minutes each.

Results

The analysis of variance for the subjects' estimates of the waiting period prior to performing on the digit symbol task yielded two significant results—the effects for test anxiety, $F(2, 108) = 3.57, p < .05$, and conditions, $F(1, 108) = 5.03, p < .01$. The test anxiety result reflected larger waiting period estimates for the high (303.8) than for the low (274.1) and middle TAS (269.5) groups. The larger high TAS estimates were mainly attributable to the high TAS group that received the achievement-orienting condition. This is shown by the fact that the mean for this group was 337.6, whereas the high TAS neutral group's mean was 270.0, $F(1, 38) = 4.31, p < .05$. Table 1 presents the mean waiting time estimates together with the mean estimates of time spent on the digit symbol task and performance scores on that task. Because there were no significant sex differences, male and female results were combined in Table 1.

The significant effects in the waiting period analysis were also significant in the analysis of subjects' estimates of time spent on the

Table 1
Mean Waiting Time and Task Time Estimates and Digit Symbol Performance Scores in Experiment 2

Condition	Waiting time ^a	Task time ^a	Performance
H-E	337.6	346.3	68.5
H-C	269.9	261.9	87.8
M-E	279.0	258.1	100.4
M-C	260.0	259.8	98.6
L-E	285.0	266.8	100.6
L-C	253.3	258.5	102.6

^a In seconds.

digit symbol task. The TAS main effect, $F(2, 108) = 5.13, p < .01$, was due to higher estimates for the high (304.1) than for the low (262.7) and middle (258.9) TAS groups. Again, the greater high TAS mean was due mainly to the high TAS achievement-oriented group. The mean for this group was 346.3, whereas the comparable low TAS control group mean was 261.9. The TAS \times Conditions interaction, $F(2, 108) = 7.81, p < .001$, was attributable to differences between the high TAS (346.3) achievement-oriented group and all other groups in the experiment (combined $M = 261.0$).

The analysis of digit symbol performance scores yielded two significant findings: for test anxiety, $F(2, 108) = 7.82, p < .001$, and Test Anxiety \times Conditions, $F(2, 108) = 3.21, p < .05$. The main effect for test anxiety was due to poorer performance for the high than for the middle and low TAS groups. This in turn was explicable largely in terms of the relatively poor performance of the high-scoring group. The high TAS achievement-orientation mean was 68.5; the mean for the high TAS control group was 87.8; and the mean for all middle and low TAS groups combined was 100.5. These results contributed to the significant TAS \times Conditions interaction.

Experiment 3

The procedural changes made in Experiment 2 led to more clear-cut results than were

^b Reflects the degree to which the subject reported experiencing interfering thoughts.

obtained in Experiment 1. The findings of the two investigations support the conclusions that not only is the performance of high TAS subjects deleteriously affected by achievement-orienting instructions, but, in addition, these subjects tend to overestimate both the duration of the test period and the period during which they wait to have their ability evaluated. This seems analogous to the tendency to exaggerate the time spent in the dentist's waiting room and in his or her office. Anticipating and going through unpleasant, frightening, or threatening experiences seem to take up a lot of time. If this interpretation is correct, the question arises: Do persons differing in anxiety fill time periods in similar or dissimilar ways? Experiment 3 was designed to provide evidence relevant to this question and to extend the generality of results obtained in Experiments 1 and 2.

In Experiment 3 the tasks used in Experiment 2 were reversed. All subjects worked on a digit symbol task prior to a waiting period and then were asked to solve a series of difficult anagrams. The period during which they were occupied with the anagrams was much longer than was the case for the postwaiting task in the earlier experiments. Following performance on the anagrams task, the subjects responded to a questionnaire dealing with their cognitive activity during that task.

Method

Subjects. The subjects were 60 female undergraduates at the University of Washington. They were divided into groups on the basis of their TAS scores, using the same cutoff points that were used in Experiments 1 and 2.

Procedure. The experimental design encompassed two factors: (a) high, middle, and low TAS scores and (b) achievement-orienting and neutral instructions. Each subject worked on the digit symbol task for 4 minutes. This was followed by a 4-minute waiting period. At the end of the waiting period, subjects performed for 18 minutes on a series of difficult anagrams. The experiment concluded with subjects responding to a questionnaire about cognitive activity while occupied with that concept-formation task. The questionnaire was a modified version of one developed by Diener and Endresen (Note 1). It dealt with the tendencies during performance to have task-irrelevant thoughts (e.g., what the experimenter thought about the subject, wondering about how others had done on the task).¹

Results

There were two significant *F*s in the analysis of waiting period time estimates, for test anxiety, $F(2, 54) = 8.31, p < .001$, and for Test Anxiety \times Conditions, $F(2, 54) = 3.31, p < .05$. The high, middle, and low TAS means were 321.8 sec, 270.4 sec, and 266.3 sec, respectively. The interaction result showed that the greater high TAS mean was attributable mostly to the high TAS group receiving achievement-orienting instructions. The mean for that group was 357.0 sec, whereas the high TAS control group mean was 286.5 sec. Table 2 presents the means of the four dependent measures for all groups in Experiment 3.

The analysis of estimates of duration of the anagrams task also yielded two significant *F*s: for test anxiety, $F(2, 54) = 3.29, p < .05$, and for Test Anxiety \times Conditions, $F(2, 54) = 3.41, p < .05$. Again, the significant results were explicable largely in terms of the relatively large estimates given by the high TAS achievement-orientation group (see Table 2). The mean for that group was 1,354.1 sec, whereas the mean for all other groups combined was 1,112.3 sec.

¹ The questionnaire is available from Irwin G. Sarason.

When an analysis was performed on the number of correct responses to the anagrams task, only the test anxiety effect was statistically significant, $F(2, 54) = 3.35, p < .05$. As the means in the third column of Table 2 show, this effect was due mainly to the relatively poor performance of the high TAS group receiving the achievement-orienting instructions.

There were two significant results in the analysis of interfering activity scores that were obtained by summing the subjects' responses to the questionnaire's 11 items. These scores reflect the degree to which the subject reported experiencing interfering thoughts. These significant results were the F for test anxiety, $F(2, 54) = 5.33, p < .01$, and for Test Anxiety \times Conditions, $F(2, 54) = 3.27, p < .05$. As column 4 of Table 2 shows, most of these significant effects were due to the high scores obtained by the high TAS achievement-orientation group, whose mean was 33.2. The mean for the high TAS control group was 24.6, and the combined mean for the middle and low TAS group was 20.3. Results for separate analyses of individual items were in every case in the same direction as the results presented for the questionnaire as a whole.

One item appended to the questionnaire asked the subject to indicate on a 7-point scale the degree to which her mind wandered while working on the anagrams task. An analysis of variance of these scores yielded significant F s for test anxiety, $F(2, 54) = 3.45, p < .05$, and for Test Anxiety \times Conditions, $F(2, 54) = 3.61, p < .05$, the directions of these results resembling those in the other analyses.

General Discussion

Looking at the total picture provided by the findings of the three studies, it appears that persons for whom tests are noxious experiences (high TAS subjects) tend to overestimate, to a greater degree than do others, both the time during which their performance is being evaluated and the period during which they are waiting for the evaluation to take place. Adding to the picture is the fact that high-test-anxious subjects performed at significantly lower levels than did low and middle scorers

when emphasis was placed on the evaluational implications of performance.

The evidence from Experiment 3 concerning cognitive interference is enlightening from the standpoint of what persons think about while working on a task. High test anxious subjects, more so than low and middle scorers, attribute to themselves preoccupations about how poorly they are doing, how other people are faring, and what the examiner will think about the subject. These findings are in line with those obtained by Diener and Endresen (Note 1). It is difficult not to interpret these preoccupations as having the effect of appreciably complicating the task at hand. Although a measure of cognitive interference during the waiting period was not obtained, it seems likely that similar preoccupations would have especially characterized high test anxious subjects at that time.

Janis (1958) has described the "work of worrying" as a step toward dealing effectively with a threatening or challenging reality situation. Arnold (1960) has also referred to worrying as a preparation for action. Although this emphasis on the positive aspects of worry is commendable, sight must not be lost of the important fact of individual differences in worrying. The person who describes himself or herself as *characteristically* being a worrier may not be taking a positive first step in coping with stress when he or she begins to worry. Rather, the individual may be creating subjectively vivid personal fictions and exaggerations that instead of being of help in the coping process, serve to exacerbate or create stress where it otherwise might not exist at all. A high score on a measure of trait anxiety may then be viewed as reflecting obsessive self-preoccupation and thereby the tendency to complicate situations that may already be sufficiently challenging. In the case of the TAS, inferences are drawn only to a defined domain of activity being evaluated.

Doob (1971) has presented a cogent, wide-ranging survey of temporal dimensions of behavior. Further research is needed on the role of a number of temporal variables in stress and anxiety. For example, although high TAS scorers in Experiment 3 described themselves as very much self-preoccupied during the 18-minute-long anagrams task, it may well be

that these covert responses were not evenly distributed throughout that time period. It would be interesting to obtain measures of cognitive interference at several points during performance. Similarly it would be valuable to have a clearer picture of cognitive activity during waiting periods. Breznitz (1971) has called attention to a process of incubation by which the stress value of a stimulus or situation is enhanced during a waiting period. The time interval between warning of an impending threat (e.g., a test) and its actual occurrence merits study as an independent variable. Of equal importance is the variable of the time filler: What happens, if anything, during the waiting interval?

Another problem of both theoretical and practical significance is the matter of how to help people gain more control over their behavior in situations requiring anticipation of, and later coping with, stress. The problem of self-preoccupation and its intrusive effects is not limited to the domain of anxiety. Some self-preoccupied persons worry, others respond covertly and overtly with anger, and still others are suspicious of potential unseen traps in the situations with which they must deal. The rapidly developing fields of cognitive training and cognitive therapy have much to contribute to the analysis, and, where desirable, to a reduction of the tendency to be self-preoccupied (Mahoney, 1974; Meichenbaum, 1972; Rimm & Masters, 1974). Training aimed at strengthening adaptive cognitive skills (e.g., planning a course of action, waiting patiently, and reducing intrusive self-preoccupation) is especially relevant in reactions to personal threat. In challenging situations—either self-imposed, as in climbing a mountain, or unexpected, as in a sudden illness—the utilization of time can be of the utmost importance. Control over one's thoughts may be the decisive factor in successfully meeting a situational challenge.

The results of the series of experiments reported here lend support to the growing interest in a Persons \times Situations approach to personality (Sarason, 1977; Sarason, Smith, & Diener, 1975). Two indices—estimates of the durations of time periods and performance—were found to be a joint function of a situational characteristic: (a) whether or not

emphasis was placed on an achievement orientation and (b) an individual difference variable, test anxiety. Other evidence from diverse fields that supports the need for an interactional psychology is now available (Magnusson & Endler, 1977). To understand and predict behavior, data are needed about both the information provided by environmental situations and the characteristics of persons who must process the information.

A Cognitive-Behavioral Treatment for Impulsivity: A Group Comparison Study

Philip C. Kendall
University of Minnesota

A. J. Finch, Jr.
Virginia Treatment Center for Children,
Richmond

From a clinic population of emotionally disturbed children, 20 children initially identified as impulsive were randomly assigned to either a cognitive-behavioral treatment group or to a control group. The treatment group received six sessions of verbal self-instructions via modeling with response-cost contingent upon errors during training, and controls received similar training without specific treatment. Although two self-report measures and teacher and staff ratings of locus of conflict did not show treatment effects, both an increase in the latency and a decrease in the error measures from the Matching Familiar Figures Test and improved teacher ratings of impulsive classroom behavior revealed positive effects due to treatment. These treatment effects remained evident at follow-up. The present study provides group-comparison evidence for the efficacy of the cognitive-behavioral treatment for modifying impulsivity.

Children are not known for their willingness to consider alternatives when it comes to making a decision. Often, they want the first candy bar they see, the toy nearest them, or anything one of their friends has. Fortunately, most children become more cautious with age. However, some children never seem to stop and think, and reflective reasoning seems alien to them—these are the impulsive children.

The cognitive dimension of reflection-impulsivity (Kagan, 1966) has been useful to describe differences in children's approaches

to problem solving. Whenever a number of response alternatives are simultaneously available and uncertainty as to the correct response is high, some children (reflectives) delay responding until the alternatives have been considered, and they have a high probability of being correct. In contrast, other children (impulsives) respond quickly with less thorough evaluation of the various possibilities and consequently make many mistakes. Using the latency and error measures of Kagan's (1966) Matching Familiar Figures (MFF) Test, children can be identified as cognitively reflective or impulsive.

This research was supported by grants from the National Institute of Mental Health (1 F31 MH-05270-01) and the Virginia Mental Health Fund to the first and second authors, respectively. Special thanks are due to James F. Hooke, who served as the sponsor for the first author's fellowship; to Donald J. Kiesler for the uniqueness of his encouragement; and to Shirley Truman for patient and responsible assistance.

At different times during the conduct and completion of the present article, the first author was affiliated with Virginia Commonwealth University, Virginia Treatment Center for Children, and the Palo Alto Veterans Administration Hospital.

Requests for reprints should be sent to Philip C. Kendall, Department of Psychology, Elliott Hall, 75 East River Road, University of Minnesota, Minneapolis, Minnesota 55455.

Among the most common behavior problems resulting in children being referred to mental health services is impulsiveness—that behavior pattern which involves a lack of inhibitory control and a tendency to respond quickly without thorough deliberation. In light of the severity of this behavior, an increasing number of studies have been directed at modifying impulsiveness in children (see Finch & Kendall, in press; Messer, 1976). Among the various methods that have been used in attempting to modify impulsivity are forced delay (Heider, 1971; Kagan, Pearson, & Welch, 1966), reinforcement contingencies

(Briggs, 1968; Finney, 1970), modeling (Debus, 1970; Denney, 1972), and instructions in strategies for scanning (Egeland, 1974; Nelson, 1969). In most of these studies, except where scanning strategies were emphasized, one or the other aspects of impulsivity (latency/errors) was modified but not both.

Other investigators (Finch, Wilkinson, Nelson, & Montgomery, 1975; Meichenbaum & Goodman, 1971) have examined verbal self-instructions training as a program for modifying impulsivity. These researchers, using cognitive training, reported changes in the desired direction for both latencies and errors.

The effects of reinforcement and response cost on cognitive style were investigated in a study by Nelson, Finch, and Hooke (1975), with results indicating that for impulsive subjects, the response-cost procedure was more effective. The utility of a response-cost procedure with impulsive children was supported by Erickson, Wyne, and Routh (1973).

Kendall and Finch (1976) combined the cognitive training procedures and the behavioral strategy of response cost into a cognitive-behavioral treatment and reported a successful case study in which both cognitive impulsivity and impulsive behavioral "switching" were reduced. In addition, the results of the cognitive-behavioral treatment generalized to the classroom and across a variety of situational tests. Even though this case study was suggestive of the utility of the cognitive-behavioral treatment, the clinical utility of such a treatment procedure needed to be demonstrated further using a clinic population in a group comparison study. The purpose of the present study was to conduct just such an examination of the effectiveness of the cognitive-behavioral approach in modifying impulsivity.

Method

Study Setting

The present study was conducted at the Virginia Treatment Center for Children, Richmond, Virginia, a university-affiliated children's psychiatric hospital. The hospital houses four living units, each with sleeping and play areas for 10 children and a respective classroom with two teachers.

Staff

Eight master's level special education teachers and 16 trained child care technicians provided ratings of behavior.

Subjects

The subjects for the present study came from all new admissions to the Virginia Treatment Center for Children between July 1, 1975, and March 1, 1976. The identification of impulsive children was based on their initial assessment scores on the MFF (Kagan, 1966). These scores, latency to first response and number of first-response errors, were compared to norms developed by us based on the performance of 195 children. The cutoff scores were as follows: Impulsives required an error rate ≥ 7 and a mean latency < 8.5 sec. Of the 51 children who were initially assessed, 20 children were identified as impulsive and were assigned to either a treatment ($n = 10$) or a control ($n = 10$) group according to a restricted randomization procedure.¹ The mean age of the children in the treatment group was 10.2 years and 11.1 years for the controls. The 20 impulsive subjects included 16 males and 4 females (8 and 2 in each group, respectively) of whom 4 were black and 16 were white (2 and 8 per group, respectively).²

Dependent Measures

Three types of dependent measures were examined: patient performance, self-report, and rating scales. Two self-report measures and three rating scales, two completed by the teachers and one by the unit personnel were used.

Patient performance. Each subject's performance on the MFF was examined at pretest, posttest, and follow-up periods. The MFF is a 12-item match-to-sample task that requires the child to choose from an array of six variants the one picture that is identical to a standard picture. This test assesses the conceptual-tempo dimension of reflection-impulsivity.

¹ The restricted randomization procedure allowed for random assignment of subjects to either the treatment or control group, with the restriction that not more than three subjects in a row be assigned to any one group. This was done to prevent having all treatment or all control subjects involved at the same time.

² Of the 20 subjects, there were 6 adjustment reactions of childhood or adolescence, 5 overanxious reactions, 5 neurotic conditions (3 depressive, 2 phobic), 2 aggressive reactions, and 2 psychotic organic brain syndrome. Relative dosages of Thorazine and/or Mellaril were prescribed for 30% of the subjects. There were no meaningful differences in the diagnoses or in the drugs for the two groups. In addition, 1 subject in each group had received Ritalin.

Latency to first response and first-response errors were recorded.

Self-report scales. The two self-report scales were the Impulsivity Scale (IS; Sutton-Smith & Rosenberg, 1959) and the Impulse Control Categorization Instrument (ICCI; Matsushima, 1964).

The IS is a 25-item (Hirschfield, 1965, revision) true-false self-report scale that assesses impulsivity defined as a tendency to be restless, to indulge in horseplay, to lose control, and to enter activities with excessive vigor. Test-retest reliability was .85 (Sutton-Smith & Rosenberg, 1959), and validity data (teacher ranking, IS scores, and classroom observation were significantly related) were acceptable (Hirschfield, 1965).

The ICCI contains 24 sentence situations to which subjects state degrees of choice between spontaneously impulsive-aggressive behavior and behavior requiring impulse control on a 4-point continuum. The scale assesses self-control over immediate action when aroused. Odd-even reliability was .93, and acceptable validity data according to an interview schedule and behavioral task persistence are provided (Matsushima, 1964).

Each child completed the inventories at the initial assessment (pretreatment), posttreatment, and follow-up periods.

Rating scales. The two rating scales used were the Impulsive Classroom Behavior Scale (ICBS; Weinreich, 1975), which was completed by the teachers, and the Locus of Conflict (LOC) Scale (Armstrong, 1971), which was completed by the unit personnel as well as the teachers.

The ICBS is a 9-item 5-point teacher rating scale that was developed by choosing the most frequently used descriptions for impulsive childhood behaviors taken from related text materials (e.g., attention span, work consistency). This scale was specifically developed for research involving the modification of impulsivity (Weinreich, 1975).

"Locus of conflict" refers to the predominant mode of impulse modulation that is exhibited by an individual. In internalization of conflict, the conflict is between impulses and their inhibition. Behaviors are rigidly controlled, and the individual experiences subjective discomfort. In contrast, externalization of conflict represents the conflict between the child's actions and the reactions that they bring about in others. Impulsive emotionally disturbed children are more likely to be rated as exhibiting externalization of conflict (Montgomery & Finch, 1975).

Each of the rating scales was completed by the respective rater at pretreatment, posttreatment, and follow-up periods.

Training Materials

There were six sets of training materials used in the present study, one for each of six therapy sessions. The six sets were (a) conceptual thinking, (b) attention to detail, (c) recognition of identities, (d) sequential recognition, (e) visual closure, and (f) visual-motor reproduction.

Set 1. This was a series of 48 plates containing four pictures, three of which were conceptually similar. The task was to "find the one that doesn't belong with the others."

Set 2. Four pictorial stimuli (in only a few cases there were nine) were presented. Two of the stimuli were identical, and the subjects were instructed to "find the pictures that match" (42 plates).

Set 3. This series of 191 plates was directed toward the recognition of identities under conditions of conceptual similarity. Each plate of two pictures required the child to verbalize, "Are these the same or are they different?"

Set 4. A series of figures (beads or other geometric figures) were presented in a sequential pattern. In each of the 68 sequences, the child was to choose from an array of alternatives "which one would come next."

Set 5. In this series of exercises, the child was presented an incomplete line drawing superimposed on a square configuration of evenly spaced dots. The child was given a pencil and was asked to "complete the drawing so that it looks symmetrical—the same on both sides. Just draw one line between any two dots." There were 50 of such visual closure tasks.

Set 6. This was a set of 56 visual-motor reproduction tasks in which the subject was asked to reproduce one design on a configuration of dots on a similar blank configuration of dots.

Period 1: Initial Assessment

All children entering the Virginia Training Center for Children were screened within a 3-day period, 10 days after their arrival at the Center. Almost without exception, children were taken from their respective classrooms between the hours of 9:00–11:30 a.m. or 1:00–2:30 p.m. Each child was initially given the opportunity to choose not to attend, but no one made such a choice. At times, however, scheduled sessions were delayed due to special events, misconduct, or illness.

During the initial assessment each child was administered the MFF, the IS, and the ICCI in a random order. Subjects were merely informed that the examiner was collecting some information and needed all the children to do these tasks. Subjects were also informed that their scores did not go to their therapists or teachers but that they were included in a larger group of scores. Children received a small candy reward for their cooperation.

Concomitant with the child's assessment session, the respective classroom teacher completed the ICBS and the LOC scale. Similarly, a randomly selected full-time unit person rated the child using the LOC scale. In order for unit ratings to be representative of unit behavior, each unit staff had to consult the records of the child's behavior on the unit for the period of time in question. Neither teachers nor unit persons were informed as to the assignment of subjects to groups, thus guaranteeing blind ratings.

Intervention

One male therapist was the individual trainer for both the treatment and control groups. All children received six 20-minute sessions during which they were exposed to the training materials and after which they, in some fashion, received a reward for their participation. Except for the instructions relating to the cognitive-behavioral treatment, subjects in both groups were given identical task instructions and performance feedback. No criterion number of tasks were set, rather, all subjects worked for 20 minutes. Thus, disregarding the cognitive-behavioral treatment, similar conditions were achieved for both subject groups.

Treatment group. Although this group received conditions similar to controls, these subjects also received specific additional training in verbal self-instructions and a response-cost procedure contingent on their errors during training.

1. Verbal self-instructions. In relation to each set of training materials, the verbal self-instructions were practiced in the following sequence: first, the therapist performed the task out loud, verbalizing out loud about possible answers and relevant aspects of the stimuli; second, the subject performed the task items with the instruction to talk out loud as the trainer had (the trainer provided guidance for overt self-instructions); next, the trainer performed the task while talking to himself in a whisper; then, the subject was told to "try the next item, and this time just whisper to yourself"; last, the therapist performed an item while modeling covert self-instructions, which, in turn, was followed by the child performing similarly.

The following sample of a self-instructional procedure was that used with the visual association tasks (Task Set 1).

Let's see now, What am I supposed to do? I'm supposed to find the one that doesn't belong with these others. I see four pictures here, so I better look at each one carefully. Okay, the first one is a clock, so is the second one. This one is a grandfather clock, but this one is a cup and saucer. So, I've got three clocks and one cup and saucer. It's the cup and saucer that doesn't belong.

In a later item done by the trainer, a planned error was made and corrected as follows: "Here we have all four animals. They're all animals . . . wait . . . this one isn't a dog, it's a lion. There, now I can correct myself before I make an error. The lion is the one that doesn't belong." Verbal self-instructions were performed during each of the six therapy sessions.

2. Response cost. At the beginning of each training session, the subject was given 10 chips and was told that the chips were his/her to keep but that he/she could lose 1 for making a mistake. An example was given, and it was checked to see that each subject understood the contingency. A reward menu hung over the work area, and on it were several categories of candy and gum purchasable with

9, 7, or 5 of the chips. Thus, it was explained to each child that he/she could use the chips to purchase a reward at the end of the session, and the more chips, the bigger and better the choice of reward. After each error on the training material, 1 chip was taken from the subject, and the inaccuracy was stated as the reason for the loss of a chip.

Control group. Although this group received similar conditions as did the treatment group, they did not receive verbal self-instructions nor was response cost contingent on errors. They were given their choice of rewards noncontingently (for their cooperation) at the end of each session.

Period 2: Posttreatment Evaluation

The posttreatment evaluation was conducted 4 weeks after the initial assessment. Subjects were told that all the children were taking the tests more than once. This was done to reduce the potential of a child perceiving the second test as due to failure on the test the first time. As in the initial assessment, subjects were taken from their respective classrooms to perform these tasks, and ratings were obtained from teachers and unit persons.

Period 3: Follow-up

Follow-up data were collected 3 months after the initial assessment (2 months after the posttreatment evaluation). Again, each child was individually administered the tasks and was told that all children were taking the tests several times. Ratings were again obtained from teachers and unit persons.

Results

Reliabilities

Patient performance. The reliability of the MFF performance was calculated using scores for all subjects who were initially assessed except those in the treatment group and those who were discharged during the course of the study ($n = 30$).³ The test-retest correlations for latency and errors at the different administrations were .72 and .78, .79 and .69, and .82 and .62 (first and second administration, second and third, and first and third, respectively). All correlations were significant ($p < .001$). Also, MFF latency and error measures correlated $-.55$, $-.75$, and $-.73$, respectively, for the three periods.

³ This group of subjects included children who were assessed at all periods and for whom data were complete, but it did not include those subjects in the treatment group. The control group was included.

Figure 1. Mean latency in seconds for the treatment and control groups at the initial assessment, post-treatment, and follow-up periods.

Self-report scales. For the IS, test-retest reliabilities were .56 ($p < .005$), .70 ($p < .001$), and .33 ($.05 < p < .10$; first and second administrations, second and third, and first and third, respectively). In similar respective order, reliabilities for the ICCI were .56, .63, and .52 (all $ps < .005$).

Rating scales. The interrater reliability of each of the rating scales was determined using Pearson product-moment correlation coefficients. Reliabilities were assessed for teachers and unit personnel by assigning randomly selected children to each of a pair of raters. Each pair of raters was assigned five children, and there were six rater pairs.

The reliability of the ICBS was .85 ($p < .01$) for the sample of students rated by the teacher pairs. The reliabilities of the three measures from the LOC scale (internalization, externalization, and total maladjustment) were assessed for teacher and unit personnel pairs both combined and separately. The combined LOC scale reliabilities were .62, .93, .91 ($ps < .005$) for the three LOC scale measures, respectively. The teacher LOC scale reliabilities were .89, .96, and .95, and the unit personnel LOC scale reliabilities were .42, .82, and .84, in the same order ($n = 5$). Thus, the reliabilities of the rating scales were favorable.⁴

Group Comparisons

To evaluate changes in the dependent measure for subjects in the treatment and con-

trol groups across the three periods, separate 2 (between-subjects) \times 3 (within-subjects) analyses of variance were conducted.⁵

Patient performance. Separate 2 \times 3 analyses of variance were conducted for latency and error measures. The latency analysis resulted in a significant groups effect, a significant periods effect, and a significant Groups \times Periods interaction, $F(1, 18) = 7.02$, $p < .01$, $F(2, 36) = 9.17$, $p < .001$, $F(2, 36) = 11.87$, $p < .001$, respectively. These results are presented in Figure 1. An analysis of simple effects (via independent t tests)⁶ indicated that although the treatment and control groups' latencies did not differ at the initial assessment period, $t(18) = .96$, the groups differed significantly at both posttreatment and follow-up, $t(18) = 3.62$, $p < .001$, $t(18) = 2.58$, $p < .02$, respectively. In addition, a related t test indicated that for the treatment group, the change in latency from initial assessment to posttreatment was significant, $t(9) = 3.69$, $p < .01$. All other t tests were nonsignificant.

The analysis of variance of the error data resulted in a significant groups effect, a significant periods effect, and a significant Groups \times Periods interaction, $F(1, 18) = 13.67$, $p < .002$, $F(2, 36) = 17.30$, $p < .001$, $F(2, 36) = 6.45$, $p < .005$, respectively. These results are presented in Figure 2.

An analysis of simple effects (via independent t tests) indicated that although the treatment and control groups' error scores did not differ at the initial assessment periods, $t(18) = .37$, the groups differed significantly at posttreatment, $t(18) = 2.92$, $p < .01$, and the groups differed significantly at follow-up, $t(18) = 1.76$, $p < .05$. The decrease in the error rate for the treatment group from the

⁴ The intercorrelations of all dependent measures, in tabular form, are available from the first author.

⁵ A table of all means and standard deviations for all the dependent measures for the treatment and control groups is available from the first author.

⁶ In the cases in which specific a priori predictions were made, one-tailed t tests were used. As a point of information, however, all ts (except one) that were either significant or not significant for one-tailed tests would have been similarly significant or not significant if two-tailed tests had been used.

initial assessment to posttreatment was significant, $t(9) = 2.52$, $p < .05$, but the decrease from posttreatment to follow-up for the control group was not significant, $t(9) = 1.17$. All other t tests were nonsignificant.

Self-report scales. The results of the 2×3 analysis of variance for the IS resulted in nonsignificant main effects for groups and for periods ($F_s < 1$) and a nonsignificant Groups \times Periods interaction, $F(2, 36) = 2.37$, $p > .10$. Similarly, the ICCI analysis resulted in nonsignificant main effects and a nonsignificant interaction, $F(1, 18) < 1$, $F(2, 36) = 1.92$, $p > .10$, $F(2, 36) < 1$, respectively.

Rating scales. The results of the 2×3 analysis of the ICBS indicated nonsignificant main effects for groups and for periods ($F_s < 1$), but the Groups \times Periods interaction was significant, $F(2, 36) = 12.19$, $p < .001$. The nature of this interaction is presented in Figure 3. An analysis of simple effects via independent t tests indicated that the treatment and control groups' ICBS ratings differed at the initial assessment, $t(18) = 4.5$, $p < .001$, with the treatment group rated as more impulsive in the classroom. Although the groups only approached being significantly different at the posttreatment period, $t(18) = 1.74$, $p < .10$ (treatment group was rated as less impulsive), the groups differed significantly at follow-up, $t(18) = 2.85$, $p < .02$, with the treated subjects rated as less impulsive in the classroom. The change in ICBS ratings for the treatment group from initial assessment to posttreatment was a significant reduction, related $t(9) = 3.70$, $p < .01$. In addition, related t tests for the change in ICBS ratings of the control subjects indicated that the increase in impulsivity from initial assessment to posttreatment was significant, $t(9) = 2.61$, $p < .05$. The increase from posttreatment to follow-up was not significant, $t(9) = 1.43$.

Three 2×3 analyses of the LOC scale data were conducted for each of the raters (unit personnel and teachers) and for each of the three LOC scale measures (internalization, externalization, and total maladjustment). The results of the unit ratings of internalization were nonsignificant (all $F_s < 1$). Unit ratings of externalization of conflict resulted in a nonsignificant groups effect and

Figure 2. Mean errors for the treatment and control groups at the initial assessment, posttreatment, and follow-up periods.

a nonsignificant periods effect, $F(1, 18) < 1$, $F(2, 36) = 3.13$, $.05 < p < .10$, respectively. The Groups \times Periods interaction was significant, $F(2, 36) = 4.22$, $p < .02$. Analyses of the simple effects via related t tests for the treatment and control groups separately resulted in nonsignificant changes across periods for the treatment group, $t_s(9) < 1$, and a significant increase for the control group from the initial assessment to posttreatment, $t(9) = 2.88$, $p < .02$, but the posttreatment decrease to follow-up was not significant, $t(9) = 1.41$. Independent t tests indicated that although the groups differed significantly on the units' initial ratings of externalization, $t(18) = 2.62$, $p < .02$, they did not differ at

Figure 3. Mean Impulsive Classroom Behavior Scale (ICBS) scores for the treatment and control group at the initial assessment, posttreatment, and follow-up periods.

the posttreatment period, $t(18) < 1$, or at the follow-up period, $t(18) = 1.25$. Thus, the significance of the above analysis is attributable to a significantly lower externalization rating for controls at the initial assessment period; no other means differed significantly.

The total maladjustment ratings made by the unit personnel were analyzed using a 2×3 analysis of variance, which resulted in nonsignificant main effects for groups and for periods, $F(1, 18) = 1.10$, $F(2, 36) = 1.09$ (in that order), and a nonsignificant Groups \times Periods interaction ($F < 1$).

The teacher ratings of locus of conflict were similarly analyzed. The results of the analysis of the internalization data were nonsignificant main effects for groups and periods and a nonsignificant interaction, $F(1, 18) < 1$, $F(2, 36) = 2.43$, $F(2, 36) = 1.14$, all $ps > .10$ (in that order). The teacher externalization of conflict ratings produced a nonsignificant groups effect, $F(1, 18) = 1.16$, $p > .10$, a significant periods effect, $F(2, 36) = 3.63$, $p < .05$, and a nonsignificant Groups \times Periods interaction, $F(2, 36) = 1.18$, $p > .10$. Similarly, the teacher total maladjustment ratings produced a nonsignificant group effect and a nonsignificant interaction ($Fs < 1$), whereas the periods main effect was significant, $F(2, 36) = 4.49$, $p < .02$.

One additional question remained unanswered by the above analyses. The question was, Does the actual number of response-cost occurrences for subjects in the treatment group correlate with improvement? To examine this, the change from the initial assessment to the posttreatment period (improvement) for both MFF latencies and errors and for ICBS scores was correlated with the respective number of response-cost consequences occurring during treatment. The correlation between response-cost occurrences and improvement in MFF latency was not significant ($r = -.36$) nor was the correlation with MFF errors ($r = .36$). The correlation of response-cost occurrences and improvement on the ICBS was .58. This relationship ($p < .06$) suggests that the more response-cost occurrences, the greater the improvement in the classroom.

Discussion

The reliabilities of the latency and error measures of the MFF provided in the present study were in the moderate to high category, and they indicate, in contrast to Finch, Dearsdorff, and Montgomery (1974), that the measures are reliable over a 3-month period. Correspondingly, the reliability of the MFF performances suggests that the reflection-impulsivity dimension is relatively stable. The teacher ratings of impulsive classroom behavior (ICBS) were highly reliable. In addition, some validation information was provided in that the ICBS was found to be a sensitive measure of the effects of treatment. Along with the brevity and simplicity of format of the ICBS, the present study provided supportive reliability and validity data that should also be considered in selecting a measure of impulsive classroom behavior.⁷

The major results of the present study substantiate the effectiveness of a cognitive-behavioral program for the modification of impulsivity in emotionally disturbed children (Kendall, 1976). In addition to the alteration of both latency and error measures of cognitive tempo, the present study found a favorable generalization of treatment to the classroom. There, as evidenced by teacher ratings, the treatment subjects displayed significantly less impulsive classroom behavior. Although teacher ratings of locus of conflict did not reflect these differences, the present results support those of Kendall and Finch (1976), and, taken together, they are considered to support the utility of the cognitive-behavioral treatment for modifying impulsivity and attaining generalization to the classroom.

It should be noted that the desired generalization of the treatment effects to the classroom is in contrast with the increase in impulsivity of the control group. Although all subjects received the "constant" treatment milieu of the Virginia Treatment Center for Children, the increase in the control subjects' impulsiveness may be due to the dynamic theoretical model of the treatment center as a whole in which the expression of feelings

⁷ A copy of the ICBS can be obtained from the first author.

are emphasized. Even though this may or may not be the treatment model of choice for overly inhibited children, it would not appear to be the desired model for impulsive children. Moreover, these findings illustrate the efficacy of examining differential treatment effectiveness for distinct groups of children (Kendall & Finch, in press).

Some of the findings of the present study have general implications. The most outstanding of these is the fact that although neither of the self-report indicants of impulsivity changed due to treatment, two measures of MFF performance and ratings of classroom behavior reflected a desirable treatment effect. The implication here is that behavior change may occur without first altering self-perceptions. An equally compelling implication is that self-report scales may be of limited utility in treatment research with children (relatively insensitive to change).

In theorizing about the effectiveness of the cognitive-behavioral treatment, one must not ignore the training materials. Indeed, in the present study in which generalization to the classroom was attained, the tasks were of the psychoeducational variety. On the other hand, if the six treatment sessions consisted of cognitive training and response-cost dealing with interpersonal situations, attaining generalization to life situations may have been more likely. Thus, although it is not impossible to conclude that the cognitive-behavioral treatment did not generalize to the units, it is likely that the training tasks are relevant in regard to the type of generalization that will be obtained (see also Kendall, 1977).

Although the present study has demonstrated that the cognitive-behavioral treatment effectively modifies impulsivity, the treatment package contains many components—modeling, self-instructions, and response cost. Future research should examine the specific components of the treatment package in an attempt to isolate the one active component or, more likely, to uncover the relative efficacy of the components.

Influence of Contextual Cues on the Efficacy of Desensitization and a Credible Placebo in Alleviating Public Speaking Anxiety

Jeffrey M. Slutsky
Roosevelt University

George J. Allen
University of Connecticut

This investigation was designed to determine the extent to which contextual cues mediated the effectiveness of systematic desensitization and a plausible placebo in alleviating public speaking anxiety. After participating in a public speaking situation that allowed the collection of self-report, physiological, and behavioral manifestations of anxiety, 67 subjects were randomly assigned to receive five sessions of either desensitization, "T scope" therapy, or no treatment. Each of these conditions was conducted in a context that either stressed the clinical relevance of the procedure or presented the procedure as a laboratory investigation of fear without therapeutic implications. Analysis of changes both between groups and within individuals indicated that desensitization reduced public speaking anxiety in both contexts, whereas the placebo was effective only in the therapeutic setting. The superiority of desensitization was most pronounced on the physiological variables. The results are interpreted as indicating support for a counterconditioning, rather than an expectancy, interpretation of desensitization.

Early documentations of the effectiveness of systematic desensitization (e.g., Lang, Lazovik, & Reynolds, 1965; Paul, 1966) were followed by numerous investigations that have sought to isolate the active therapeutic ingredients of this procedure. One critical area that has received much recent attention is the influence of cognitive factors on the outcomes engendered by desensitization. Three general research strategies have generally been used in investigating this complex theoretical issue.

The first involves comparing desensitization against various placebo manipulations. The outcomes of this strategy have been inconsistent. Paul (1966) and Davison (1968) demonstrated the superiority of desensitization with evidence that supported a counterconditioning interpretation. Other investigators, however, have failed to differentiate

the effects of desensitization and placebos in alleviating test anxiety (Allen, 1971) or small-animal phobias (McReynolds, Barnes, Brooks, & Rehaven, 1973; Tori & Worell, 1973). This inconsistency may be partly due to differences in the perceived credibility of the treatment and placebo procedures that have been used (Borkovec & Nau, 1972).

A variant of this first strategy involves providing instructional sets to augment the efficacy of desensitization within a therapeutic context. In general, the results produced within this framework suggest that such manipulations yield very modest effects (McGlynn & Mapp, 1970; Woy & Efran, 1972).

The third and potentially most useful line of investigation involves presenting desensitization as either a therapeutically relevant treatment or a nonclinical laboratory procedure by means of instructional and contextual cues. Utilizing this paradigm, several studies (Miller, 1972; Rosen, 1974) have indicated that desensitization is more effective when presented as a clinically useful technique. In

addition, Tori and Worell (1973) found no differences between desensitization conducted in a laboratory context and a plausible placebo procedure.

Several systematic influences run through these three studies that limit their adequacy in providing a crucial test of the competing theoretical models of desensitization. First, both Miller and Rosen reported that a number of subjects in their laboratory conditions evidenced awareness of the therapeutic qualities of desensitization. More importantly, all three investigations examined small-animal phobias, which lessens their relevance for two reasons. Bernstein (1973) has clearly demonstrated the influence of contextual cues in both the selection of animal phobias and their response patterns on self-report and behavioral avoidance measures. Borkovec (in press) provides impressive evidence indicating that exposure to fearful animal stimuli does not evoke extreme physiological activation. These researchers advocate the use of various interpersonal anxieties in analogue investigations of desensitization.

The present study examines the efficacy of desensitization and a highly credible placebo procedure administered within separate clinical and laboratory contexts in alleviating public speaking anxiety. The first and third research strategies were combined to clarify the extent to which contextual cues influence the specific and nonspecific effects of these procedures and to provide a test of the two dominant models of desensitization. Specifically, demonstrating that desensitization is superior to a placebo in reducing self-report, behavioral, and especially physiological indices of anxiety across contexts would support a counterconditioning explanation, whereas interactions between treatments and settings would argue for a cognitive-expectancy interpretation.

Method

Subjects

Of slightly over 1,500 students in an introductory psychology course who were offered the opportunity to participate in a program designed to improve public speaking, 116 expressed interest and 75 met several selection criteria including acknowledging a

high level of fear of public speaking on Geer's (1965) Fear Survey Schedule, attending a pretreatment screening session, and providing a monetary deposit as a guarantee that treatment sessions would be attended. Complete data were collected from a total of 67 subjects, 35 of whom participated in the clinic phase of the experiment. The remaining 32 subjects were told that they could not be accommodated in the therapy program because it was filled. Approximately 5 weeks later, after the therapy phase had been completed, these subjects were asked to take part in an ostensibly independent laboratory study of physiological concomitants of anxiety.

The deposits of these latter participants were returned when they were refused treatment, and they were later paid for their participation as research subjects. The participants averaged 18.6 years of age and were predominantly freshmen women.

General Experimental Design

Table 1 provides an overview of the general experimental design. The experiment was conducted in two separate contexts in two independent phases with different subjects studied in each. During the first phase, subjects assigned to the clinical setting were screened and received five 50-minute sessions of either desensitization or a placebo therapy administered by one of two advanced graduate students. Immediately after completion of this phase, the graduate students carried out identical treatment procedures in a research context with those subjects assigned to the laboratory setting. Assessment sessions were conducted before and after each phase, and two no-treatment groups were included. These control subjects were informed that they could not be accommodated in the program for which they were eligible, but they were asked to participate in the posttreatment assessment sessions. A debriefing session for all subjects was held following completion of the laboratory phase. Those subjects who received no treatment or some other ineffective treatment were then offered therapy. Thus, the basic design involved six independent groups in a complete factorial crossing of three treatment conditions in two contexts with repeated measurement before and after intervention. The therapeutic procedures were crossed with two therapists.

Process and Outcome Measures

The screening and posttreatment evaluation sessions closely followed Paul's (1966) procedures. Before these assessments, a measure of trait anxiety (Spielberger, Gorsuch, & Lushene, 1970) was obtained. After the program had been explained, participants were required to give a 2.5-min speech on an assigned topic. Immediately before the speech, each subject completed the Anxiety Differential (Husek & Alexander, 1963) and a questionnaire

form, devised by the present authors, which provided indications of state anxiety and somatic/emotional turmoil, respectively. Two physiological measures, a 15-sec pulse rate and a palmar sweat print, were also collected at this time. During the speech, two trained observers noted behavioral manifestations of anxiety on Paul's (1966) Timed Behavioral Checklist. Following the speech, which was given before an audience of 7-10, each subject completed the Personal Report of Confidence as a Speaker, as modified by Paul (1966).

Following each of the treatment sessions, subjects rated their perceptions of the interaction along seven 7-point semantic differential scales (e.g., tense-relaxed, fast-slow). Ratings of relaxation during image visualization, anxiety evoked by images, and clarity of images presented during the second through fifth sessions were made along 6-point dimensions. A termination questionnaire was also administered to assess subject involvement in the program as well as perceptions of the therapist/experimenter on nine bipolar adjectives.

Experimental Groups

Subjects were randomly assigned to three conditions, each of which was replicated in two contexts. All treated participants were attached to a polygraph that provided prerecorded printouts, which were shown at the end of each session. Subjects in the clinical context were told that the printouts indicated that they were responding well to treatment, whereas in the laboratory context, this feedback was interpreted as indicating support for the research hypotheses. Thus, even though participants were led to believe that they were either "good" clients or good subjects, positive expectations of the *therapeutic efficacy* of the procedures were induced only in the clinical setting.

Desensitization/clinical context. Subjects assigned to this condition came to a departmental therapy clinic and were informed that they would be receiving a demonstrably effective form of therapy that would ameliorate their fear of public speaking. The treatment rationale described by Paul (1966) was presented, and his procedures were replicated with regard to training relaxation, constructing a hierarchy, and desensitization proper.

Desensitization/laboratory context. Treatment was conducted in a laboratory setting. Following Leitenberg, Agras, Barlow, and Oliveau (1969), subjects were told that the experimenter was interested in studying the visualization of anxiety-producing images and concomitant physiological reactions. Relaxation was presented as a means of facilitating visualization. The actual treatment procedures paralleled those used in the clinical setting.

Placebo/clinical context. This placebo manipulation replicated the procedures used by Tori and Worell (1973). Subjects learned that they would be presented with tachistoscopic scenes of individuals gesticulating while speaking. The rationale explained how viewing subliminal scenes while relaxed would

16-21		Treatment
22-23		Posttreatment assessment

Note. Subjects were selected during Weeks 1-3.

facilitate the acquisition of more adaptive public speaking skills. Irrelevant images were actually used.

Placebo/laboratory context. The same tachistoscopic procedures were used with the rationale stressing the experimenter's interest in the effects of subliminal exposure to stress-related images. It was intimated that such stimuli would have relatively minor impact.

No treatment/clinical context. This group participated in the assessment procedures before and after the therapy phase. Subjects were informed during the pretreatment assessment that they could not be accommodated in the current program and were promised therapy at a later date.

No treatment/laboratory context. After the screening session, these subjects were scheduled to return for a second evaluation at the end of the research program.

Results

Comparability of the Experimental Conditions

To ascertain whether any systematic pretreatment differences between the groups existed, seven Treatment \times Context \times Therapist analyses of variance were computed. Since only 4 of 49 F tests were significant and since they did not fall into a consistent pattern, the essential equivalence of the groups was assumed.

Reliability Considerations

A pair of raters independently matched each palmar sweat print against 15 specimens to provide quantifiable data. Interobserver reliabilities were .94 and .90 for judgments

made before and after treatment. The usable score for each print was obtained by averaging the two ratings. Each subject's pulse was converted into beats per minute by multiplying by four. Three pairs of observers were trained to rate anxiety on the Timed Behavioral Checklist. Interrater reliabilities of total scores were .79, .87, and .86 for the observer dyads. The scores of both raters were summed to provide an indication of the behavioral manifestations of public speaking anxiety.

Overall Effectiveness of the Manipulations

Means of the major dependent variables before and after the experimental manipulations are presented in Table 2. Treatment \times Context \times Time analyses of variance indicated significant effects for repeated testing on the Anxiety Differential, the questionnaire form, the Personal Report of Confidence as a Speaker, and the Timed Behavioral Checklist. Treatment \times Time interactions were significant for state anxiety, $F(2, 61) = 3.55$, $p < .05$, the questionnaire form, $F(2, 61) = 3.18$, $p < .05$, and showed tendencies on the Personal Report of Confidence as a Speaker, $F(2, 61) = 2.87$, $p < .07$, and pulse rate, $F(2, 61) = 2.67$, $p < .08$. These interactions were largely due to greater improvement in the

desensitized subjects. Reliable Context \times Time interactions on the Anxiety Differential and the questionnaire form indicated that the clinic context was associated with greater anxiety reduction.

The reliability of improvement within each condition was assessed by correlated t tests, which are presented in Table 3.

Desensitization was the only treatment that produced significant improvement on self-reported, behaviorally observable, and, most importantly, physiologically measured anxiety. The placebo led to improved self-reported and behavioral functioning when conducted in a clinical context, but it was no more effective than the passage of time when administered under the guise of research. The no-treatment control groups generally showed little change.

Analysis of Individual Changes

To investigate the effects of the manipulations on the performance of individual subjects, residual change scores were computed by subtracting actual posttreatment scores from the predicted score determined by regression analysis. This procedure is analogous to an analysis of covariance in that it equates existing between-group differences and removes changes due to statistical regression. Reliable improvement or deterioration for

each subject was defined as having a residual change score either greater or less than 1.96 times the standard error of measurement for that variable (the 95% confidence interval). Table 4 presents the percentages of subjects in each treatment group who manifested significant improvement or deterioration on each variable as a result of participating in the experiment.

These data generally support the conclusions drawn from prior analyses. Subjects receiving desensitization in both contexts or the placebo in the clinical setting showed the highest rate of improvement on the self-report measures, with higher rates of deterioration being noted for the remaining groups. The extreme variability generated by the clinical placebo procedure is noteworthy. Although the improvement figures parallel those produced by desensitization, deterioration percentages were of a higher magnitude. Desensitization also produced the highest percentages of improvement and the smallest amount of deterioration on the physiological and behavioral measures.

Analysis of items measuring subjects' perceptions of the treatment sessions were non-significant with the exception of one reliable difference relating to the level of activity between the therapists. Responses to the termi-

nation questionnaire revealed that subjects in the desensitization groups believed their visualizations to be significantly clearer, $F(1, 33) = 50.17, p < .001$, and more anxiety evoking, $F(1, 33) = 12.50, p < .01$, than participants in the placebo conditions. In addition, subjects in the clinical context viewed their therapists as more active and organized and reported greater expectations for therapeutic improvement, $F(1, 33) = 25.36, p < .001$, than subjects in the research phase. These therapist differences did not affect performance on the outcome measures, however.

Discussion

Perhaps the most important conclusion to be drawn from this study is the superiority of desensitization in reducing self-reported and behaviorally measured anxiety and in lowering physiological arousal. The effects of this treatment were robust in terms of their insensitivity to contextual cues. Subjects who were desensitized in a research setting manifested therapeutically relevant gains, in spite of the fact that they viewed the procedure as having little utility in this regard. Setting factors, on the other hand, exercised a powerful effect on the outcomes produced by the placebo manipulation, with this procedure be-

ing as efficacious as desensitization in a therapeutic context but not reliably better than no treatment in a research-related atmosphere.

These findings seem useful in placing some of the previously reviewed discrepancies into a coherent perspective. It appears that many of the studies that reported differences between desensitization and placebo treatments (e.g., Davison, 1968; Paul, 1966) used pseudo-therapeutic manipulations of low credibility (Borkovec & Nau, 1972). Highly plausible placebos, such as the one developed by Tori and Worell (1973), seem to engender positive outcomes that match those produced by desensitization but only when administered in clinical contexts. Failure to find differences between these two types of treatment in the Tori and Worell study might well have been due to contextual differences whereby desensitization was presented only as a laboratory procedure while the therapeutic relevance of the placebo was stressed.

Thus it appears that embedding placebo manipulations in a therapeutic context is a necessary but not a sufficient condition for insuring their effectiveness.

The theoretical import of these findings in-

volves the support that they provide for Wolpe's (1958) counterconditioning model of desensitization. The study provides further evidence that this therapeutic procedure has a potent effect on alleviating anxiety related to a clinically relevant problem and is relatively insensitive to cognitive influences. Modification of this conclusion awaits the resolution of many problems in the expectancy literature (Wilkins, 1973).

A New Measure of Psychological Androgyny Based on the Personality Research Form

Juris I. Berzins, Martha A. Welling, and Robert E. Wetter
University of Kentucky

In line with recent reconceptualizations of psychological masculinity and femininity as independent dimensions, the present article describes the development and validation of the PRF ANDRO scale whose Masculinity and Femininity subscales were drawn, on the basis of theoretical definitions, from the item pool of Jackson's Personality Research Form. Using data obtained from over 2,000 college students, the subscales of the PRF ANDRO scale are shown to be independent, reliable, minimally related to socially desirable responding, and substantially related to the corresponding subscales of Bem's Sex Role Inventory (correlations between .50 and .65) and to major personality dimensions. Further evidence of construct validity is adduced from the score patterns in 18 different samples that include clinical and other noncollege groups. Since the PRF ANDRO scale can be scored from the answer sheets of the Personality Research Form, other investigators may reanalyze prior studies with particular regard to the proposition that high levels of Masculinity and Femininity, jointly denoting psychological androgyny, predict greater interpersonal competence and transsituational adaptability than do traditionally sex-typed role orientations.

In recent years, the conceptualization and measurement of sex roles have undergone radical changes (Bem, 1974, 1976; Block, 1973; Constantinople, 1973; Kaplan & Bean, 1976; Pleck, 1975; Spence, Helmreich, & Stapp, 1975). The once self-evident assumption that high levels of sex typing promote psychological adjustment has come under increasingly sharp theoretical and empirical attack (e.g., Bem, 1976; Bem & Bem, 1970); behaviors thought to be "natural" correlates of biological sex differences, to be exemplified by "appropriately" masculine men and femi-

nine women, have lost their stereotypic potency. Rather, members of the human liberation movement argue that depending on the situation, the behavioral repertoires of healthy adults of both sexes can encompass behaviors previously assigned to the sexes differentially. The concept of psychological androgyny—the integration of culturally masculine and feminine attributes into one's self-definition and behavior—has become ascendant in recent perspectives on mental health (e.g., Bem, 1976; Kaplan, 1976).

We wish to express our appreciation to Douglas N. Jackson and Research Psychologists Press for permitting us to reproduce items from the Personality Research Form in our research. We are also grateful for the normative data contributed by Joyce Cheney, Claudia Dispennette, Charles Kondo, Kerry McIntosh, David Mee Lee, Vincent Nerviano, Wesley Ross, Phillip Russell, Connie Weet, and others.

Requests for reprints, unpublished materials, and a manual for the use of the PRF ANDRO scale should be sent to Juris I. Berzins, Department of Psychology, University of Kentucky, Lexington, Kentucky 40506.

Traditional measures of psychological masculinity-femininity, however, have been predicated on the assumptions that masculinity and femininity define the endpoints of a single bipolar dimension (the sexes as "opposites") and that measures of this dimension are best constructed by aggregating various items that show large endorsement differences between the sexes or between persons of differing sexual preferences (Constantinople, 1973). Adherence to these assumptions has generated measures that create virtually nonoverlapping distributions of scores for men and women, with the implication that the majority of per-

sons who score within the range typical for their gender are "appropriately sex typed," whereas the few persons who score outside that range presumably exemplify sex role confusion, deviance, ambivalence, or maladjustment. But it is clear that defining masculinity as "not femininity" and femininity as "not masculinity" precludes characterizing persons as *both* feminine and masculine (androgynous) or, logically, as *neither*. To permit the latter sex role categories to emerge, at least two independent dimensions, one for masculinity and one for femininity, are needed. If psychological masculinity and femininity are construed as independent dimensions of human functioning (albeit dimensions whose components in many cultures have been regarded as differentially desirable in men and women), then one could characterize at least some individuals as *both* masculine and feminine, instrumental and expressive (Parsons & Bales, 1955), assertive and yielding (Bem, 1974), or agentic and communal (Bakan, 1966; Block, 1973; Carlson, 1971).

Three self-report measures that embody this dualistic conception of sex roles have already been published. The Bem Sex-Role Inventory (BSRI; Bem, 1974) contains separate Masculinity and Femininity subscales, each comprised of 20 adjectives (7-point response format) judged differentially desirable for men and women in our society. The BSRI has been used to select participants in experiments that have demonstrated the greater behavioral flexibility of androgynous persons, relative to sex-typed ones, across several situations (see Bem, 1976). Spence et al. (1975) developed separate male-valued and female-valued subscales of a Personal Attributes Questionnaire, with each subscale comprised of 18 or more bipolar adjectives (5-point format) representing attributes judged stereotypically masculine or feminine but considered desirable for both sexes. Heilbrun (1976) extracted Masculinity and Femininity subscales from an earlier bipolar composite index based on the Adjective Check List (Cosentino & Heilbrun, 1964); items had been selected originally by contrasting the endorsement proportions of men identified with masculine fathers and women identified with feminine

mothers. All three instruments use a quadripartite classification of persons—high masculine/high feminine (androgynous), high masculine/low feminine (masculine typed), low masculine/high feminine (feminine typed), and low masculine/low feminine (undifferentiated or indeterminate).

The present article describes the development and psychometric credentials of a fourth instrument. It was inspired by and drew its theoretical rationale from Bem's BSRI but was developed from the items of a widely used multiscale personality inventory, the Personality Research Form (PRF; Jackson, 1967). Although various aspects of the validity of the Masculinity and Femininity constructs embodied in the subscales of this new instrument, the PRF ANDRO scale, have already been investigated in several contexts (Kelly & Worell, 1976; Berzins, Note 1; Welling, Note 2; Wetter, Note 3; Woods, Note 4), the Masculinity and Femininity subscales of the BSRI are regarded as the principal criteria for initial assessment of convergent validity in this article.

Rationale for Item Selection

The rationale outlined by Bem (1974) in constructing the BSRI included provisions for (a) separate Masculinity and Femininity scales, (b) items selected on the basis of *sex-typed* desirability (e.g., in American society, a masculine characteristic should be judged more desirable for a man than for a woman), and (c) items with generally positive content. We chose to apply this rationale to the PRF item pool, since we had conducted extensive research with this instrument and, were scale development successful, accumulated data could be reanalyzed.

The PRF is a multitrait inventory based on Murray's need theory. Form AA of the PRF (Jackson, 1967) contains 20 content scales (Abasement, Achievement, Affiliation, Aggression, Autonomy, Change, Cognitive Structure, Defence, Dominance, Endurance, Exhibition, Harmavoidance, Impulsivity, Nurturance, Order, Play, Sentience, Social Recognition, Succorance, Understanding) and two validity scales (Infrequency and Desirabil-

ity). Each scale contains 20 items, 10 keyed true and 10 false. Reviews of the PRF attest to its unusually good reliability and validity (cf. Wiggins, 1973).

To select potential Masculinity and Femininity items from the PRF content scale item pool (400 items), the original PRF scale placement of the items was disregarded, but their content was evaluated for (a) consistency with Bem's rationale and (b) consistency with rationally derived abstract definitions of the main content themes of Bem's Masculinity and Femininity scales. In the latter regard, the BSRI Masculinity scale was held to depict a dominant-instrumental dimension comprised of themes of social-intellectual ascendancy, autonomy, and orientation toward risk; the BSRI Femininity scale was judged to revolve around a nurturant-expressive dimension, containing themes of nurturance, affiliative-expressive concerns, and self-subordination. PRF items consistent with the masculine themes consequently were selected if they appeared more desirable in men than in women, whereas items consistent with the feminine themes were selected if more desirable in women than in men. To facilitate some degree of control over acquiescent responding in the eventual scales, both true- and false-keyed items were considered. Sixty-four (32 masculine, 32 feminine) PRF items were provisionally selected in this manner by the first two authors. These items turned out to have been drawn from 16 of the 20 PRF content scales (no items from Change, Cognitive Structure, Order, or Sentience), with 9 Masculinity items drawn from the Dominance scale, 11 Femininity items from the Nurturance scale, and no more than 6 items from any other scale. In subsequent item analyses, the provisional scales were shortened to 29 Masculinity items (19 keyed true, 10 false) and 27 Femininity items (17 keyed true, 10 false).

Sex-Typed Desirability Ratings

To evaluate the consensuality of the authors' judgments regarding the sex-typed desirability of the final 56 items, a separate study was conducted (Wicher, Note 5). When

scoring direction is adjusted appropriately (false-keyed items reflected), Masculinity scale items should be judged more desirable "for a man" than "for a woman," whereas Femininity scale items should be judged oppositely. Using Bem's (1974) rating format (7-point scales ranging from "not at all desirable" to "extremely desirable"), 177 students in introductory psychology (61 men, 116 women) rated all items; 30 men and 57 women judged the items for a man; 31 men and 59 women judged them for a woman; no judge rated both target sexes. Each PRF item was presented to judges in its full form and was followed by the question, "In American society, how desirable is it for a MAN (alternately, WOMAN) to mark this item TRUE?" Judges were cautioned to make normative (descriptive) rather than prescriptive judgments.

A 2 (judge sex) \times 2 (target sex) analysis of variance disclosed that the mean desirability of Masculinity items was 5.35 when the target was a man but was 3.29 when the target was a woman, $F(1, 173) = 497.57, p < .0001$. The mean desirability of Femininity items, in turn, was 5.28 when the target was a woman but 3.58 when the target was a man, $F(1, 173) = 392.01, p < .0001$. In neither analysis were effects associated with judge sex or the Judge \times Target Sex interaction significant. Analysis of individual items showed that all 56 target sex differences were in the expected direction, with 53 differences significant beyond the .05 level and 50 beyond the .001 level.

Participants and Measures used in Psychometric Analyses

The main portion of this article is based on two samples. Sample 1 ($n = 1160$) was comprised largely of students in introductory psychology at the University of Kentucky in 1974-1975. The mean age was about 20. Sample 1 members completed (a) the 85-item Interpersonal Disposition Inventory (IDI) comprised of the 56 items of the PRF ANDRO scale, the 20-item PRF Desirability scale, 5 items from the PRF Infrequency scale (if more than one of these was answered in the keyed direction, the respondent was excluded

Femininity	14.31	3.57	18.37	3.60	312.29*

Note. Sample 1 is comprised of 457 men and 703 women; Sample 2, of 434 men and 552 women.

* $p < .0001$.

from analyses) and 4 fillers and (b) the 60-item BSRI. During the second semester, participants also completed (a) a personal attitudes survey, which included, in alternating order, the 33 items of the Marlowe-Crowne Social Desirability Scale (Crowne & Marlowe, 1964) and the 33 items of a self-esteem scale designed especially for this study as a measure of generalized self-evaluation (Welling, 1976; Wetter, Note 3) and (b) Rotter's Internal-External Locus of Control Scale (Rotter, 1966).

Sample 2 ($n = 986$) consisted of introductory psychology students tested in 1970. Mean age was 18.7. Their responses to the full PRF (Form AA) were scored for the Masculinity and Femininity subscales of the PRF ANDRO scale. It should be noted that the order of appearance and the context of PRF ANDRO scale items differ in the regular PRF and the IDI.

Normative Data

Table 1 presents normative data and tests for sex differences for the PRF Masculinity and Femininity scales when scored from the IDI (Sample 1) and the full PRF (Sample 2). Although sex differences in item endorsement had played no part in item selection, in both samples men exceeded women on the Masculinity scale and women exceeded men on the Femininity scale (both p s $< .0001$); the differences approximate or exceed one standard deviation in each instance.¹ Analysis of individual items revealed that 83.9% (47/56) of these showed significant ($p < .05$)

differences in the expected direction; no items were significant in the opposite direction. As one would expect if most individuals were sex typed in our culture, men also scored higher on the Masculinity scale than on the Femininity scale, and women showed an even greater difference in the opposite direction.

Although Table 1 also reveals some differences between the two samples (e.g., Sample 1 women scored higher than Sample 2 women on Masculinity), such differences may arise with equal plausibility from differences in age or academic level (Sample 1 is older), the different contexts in which items were embedded (IDI vs. PRF), or cultural changes (1970 vs. 1974-1975).

Scale Independence and Reliability

With regard to the theoretical requirement that Masculinity and Femininity scores be orthogonal (rather than strongly and negatively correlated), the correlations between the two scales in Samples 1 and 2, respectively, were $-.05$ and $-.11$ for men and $-.16$ and $-.24$ for women.

Estimates of the retest stability of scale scores, using an interval of approximately 3

¹ Users of the BSRI should note that on the BSRI Masculinity scale, the 452 men obtained a $M = 5.07$, $SD = .65$; the 703 women, $M = 4.54$, $SD = .69$; $F(1, 1153) = 172.66$, $p < .0001$. On the BSRI Femininity scale, men had a $M = 4.56$, $SD = .53$; women, $M = 5.14$, $SD = .53$; $F(1, 1153) = 322.09$, $p < .0001$. Alpha coefficients were .86 for Masculinity and .80 for Femininity.

weeks, were obtained from a separate sample of 55 men and 82 women enrolled in the first author's Personality classes; these students were unaware of our interest in sex roles at the time of testing. Rather than completing the same instrument twice, about half of the students completed the entire PRF in class and the IDI at home; the other half reversed the sequence. Given the differing item contexts and conditions of administration, the obtained retest coefficients ($r = .81$ for both the Masculinity and Femininity scales) should be regarded as conservative.

Although the explicit multidimensional definitions of Masculinity and Femininity that were used tend to lower interitem correlations and the resulting scale homogeneities, item-total correlations in eight independent analyses (2 Scales \times 2 Samples \times 2 Sexes) ranged between .12 and .52 (all $ps < .01$), with median values ranging from .28 to .35. The alpha coefficients for Masculinity were .76 in Sample 1 and .79 in Sample 2. For Femininity, the coefficients were .67 in Sample 1 and .70 in Sample 2.

Sex Role Classification

Following the procedure used by Bem (1977) and Spence et al. (1975), we performed median splits on the distributions of scores on the Masculinity and Femininity scales separately, after combining the sexes. In this manner, Masculinity scores of 15 or greater and 14 or less were designated as high and low, respectively; the comparable Femininity scale values were 17 or greater and 16 or less. The categories created thereby were termed *androgynous* (high masculinity/high femininity), *masculine typed* (high masculinity/low femininity), *feminine typed* (low masculinity/high femininity), and *indeterminate* (low on both). When Samples 1 and 2 were pooled, the resulting classification percentages for men and women, respectively, were androgynous, 18.7% and 20.3%; masculine typed, 48.7% and 13.6%; feminine typed, 10.4% and 48.1%; indeterminate, 22.1% and 17.9%. Roughly speaking, then, 1 of every 2 persons is "appropriately" sex typed, 1 in 5 is androgynous, 1 in 5 is indeterminate, and only 1 in 10 is "cross-typed."

Content Dimensions in the BSRI and the PRF ANDRO Scale

Since a rational analysis of the content themes of the BSRI gave us the inspiration to develop the PRF ANDRO scale, it is appropriate to examine empirically the extent to which such themes emerged in the self-descriptions of Sample 1 participants. Using the data of the 1,155 persons who had completed the BSRI, the 40 BSRI items and gender (male = 0, female = 1) were intercorrelated and factored by the method of principal components (unities in the diagonal), followed by varimax rotation. Application of Cattell's scree test to the nine eigenvalues greater than 1.0 suggested that eight factors (56% of total variance) should be rotated.

In terms of saliently ($r > .50$) loading items (shown in parentheses), the four factors defined exclusively by BSRI Masculinity items refer to Social Ascendancy (acts as a leader, dominant, has leadership abilities, forceful, aggressive, assertive, strong personality), Autonomy (independent, self-sufficient, self-reliant, individualistic), Intellectual Ascendancy (defends own beliefs, willing to take a stand), and Physical Boldness (athletic, competitive). The three factors defined by BSRI Femininity items describe Nurturant Affiliation (tender, compassionate, warm, gentle, sympathetic, affectionate, understanding, sensitive to the needs of others, eager to soothe hurt feelings), Self-subordination (childlike, gullible, flatterable), and Introversion (soft-spoken, shy). The eighth factor refers only to respondents' gender (.88) and the items *feminine* (.85) and *masculine* (−.87), indicating that the latter items are synonymous with biological gender. Overall, these results offer surprisingly good support for our initial conceptual analyses.

A comparable analysis conducted with the 56 PRF ANDRO scale items (plus gender) yielded 18 eigenvalues greater than 1.0.² Ap-

² The larger number of eigenvalues for the PRF ANDRO scale, as compared to the BSRI, is a function of the larger number of items, the lesser item reliabilities associated with true-false versus multi-point scales, and possibly the lack of balancing for acquiescence in the BSRI.

plication of the scree test suggested the advisability of rotating only eight factors (34% of variance), of which seven were interpreted.

The four factors defined exclusively by PRF Masculinity items referred to Social-Intellectual Ascendancy (e.g., "I seek out positions of authority"), Autonomy (e.g., "If I have a problem, I like to work it out alone"), Orientation Toward Risk (e.g., "I avoid some sports and hobbies because of their dangerous nature," keyed false), and Individualism (e.g., "I don't care if my clothes are unstylish, as long as I like them"). The two factors defined exclusively by PRF Femininity items addressed Nurturance (e.g., "When I see a baby, I often ask to hold him"), and a blend of Affiliative Concerns and Self-subordination (e.g., "I like to be with people who assume a protective attitude toward me"). The former (Nurturance) dimension showed the highest loading for gender (.70) among the factors. The seventh factor included three Femininity items (e.g., "I am usually the first to offer a helping hand when it is needed") and two Masculinity items (e.g., "When I see a new invention, I attempt to find out how it works"), collectively denoting Helpful Initiative.

Although both the BSRI and the PRF scales are clearly multidimensional, the similarities between the main themes of the respective Masculinity and Femininity subscales suggest that convergent validity coefficients should be appreciable.

Convergent and Discriminant Validity

To determine the convergences between the PRF and BSRI measures of Masculinity and Femininity as well as their respective independence from socially desirable responding (assessed by the PRF, BSRI, and Marlowe-Crowne Desirability scales), and to examine their relation to measures of self-esteem and beliefs in internal-external locus of reinforcement, the measures administered to Sample 1 were intercorrelated and are presented in Table 2.

Table 2.

The convergent validity coefficients for Masculinity were .60 for men and .65 for women; for Femininity, they were .52 and

** $p < .01$.

.50, respectively. (For the sexes combined, they were .68 and .61). These values indicate substantial similarities between the constructs underlying the total scores in these instruments. Analysis of individual items, in fact, showed that all PRF Masculinity scale items correlated significantly ($Mdn = .23$, all $ps < .001$) with BSRI Masculinity scores; similarly, all PRF Femininity items correlated significantly ($Mdn = .22$, all $ps < .04$ or better) with BSRI Femininity scores. Conversely, all BSRI Masculinity items and all but one BSRI Femininity item related significantly to their respective PRF counterpart scores (Masculinity $Mdn = .37$, Femininity $Mdn = .33$, all $ps < .02$ or better).

Excluding the BSRI items *masculine* and *feminine* (which refer to gender only), the high scorer on the PRF Masculinity scale is described by the 10 best BSRI items as acts as a leader, has leadership abilities, dominant, willing to take a stand, willing to take risks, independent, forceful, competitive, strong personality, and individualistic. The high scorer on the PRF Femininity scale, in turn, can be described as sympathetic, loves children, eager to soothe hurt feelings, sensitive to the needs of others, tender, compassionate, affectionate, gentle, warm, and understanding.

With regard to discriminant validity, the correlations of the sex role measures with the three Desirability scales (Measures 5, 6, and 7 in Table 2) are generally positive and low. For the two PRF scales, the 12 relevant coefficients range from .00 to .29; for the BSRI scales, they range from .02 to .32. For both instruments, consequently, socially desirable responding explains very little variance in scores.

Inspection of the correlations involving the Self-esteem scale, however, reveals that scores on both Masculinity scales are moderately related to favorable self-evaluations (for the PRF Masculinity scale, .36 among men and .38 among women; for the BSRI, .39 among men, .44 among women). In contrast, the relation of both Femininity scales to self-esteem is negligible, with coefficients ranging from $-.06$ to $.13$. Differences among sex role categories in self-esteem (Spence et al., 1975; Welling, 1976; Wetter, Note 3), consequently,

are more likely to be related to variations in Masculinity than in Femininity scores when the PRF ANDRO or the BSRI measures are used.

Finally, it is apparent that apart from low-order correlations suggesting a positive relation of Masculinity scores to beliefs in internal control, significant among men and for the BSRI among women, little variance is shared between these sex role measures and beliefs in internal-external control. As noted elsewhere (Berzins, Note 6), the best predictor of locus of control is the PRF Desirability scale, probably because it contains an appreciable self-esteem component (see Table 2) and has in fact been construed as a measure of self-esteem in a prior study (Berzins, Barnes, Cohen, & Ross, 1971).

Sex Role Categories and Personality Dimensions

Since the members of Sample 2 had completed the entire PRF, it was possible to examine the relation of their PRF ANDRO scale scores to the principal components of the 20 PRF scales. The latter were extracted in an earlier analysis (Berzins, Note 6), but they require brief description. Following standardization of PRF content scales within sex, the matrix was factored for the sexes separately and combined, with varimax rotation. In all three analyses, five components showed eigenvalues greater than 1.0 (explaining 64.4% of total variance in the combined analysis); between-sex congruency coefficients (Harman, 1967) ranged from .85 to .94; and invariance coefficients (Pinneau & Newhouse, 1964), from .75 to .93. In the combined analysis ($n = 986$), the components and their principal markers (loadings $> .60$) were Impulsivity (Impulsivity, .79; Cognitive Structure, $-.81$; Order, $-.76$); Dependency (Succorance, .86; Autonomy, $-.74$); Social Poise (Exhibition, .78; Affiliation, .76; Dominance, .65); Defensiveness (Defendence, .81; Aggression, .76; Abasement, $-.64$); and Intellectuality (Sentience, .80; Understanding, .74). Component scores ($M = 50$, $SD = 10$) derived from this solution by multiple regression should render less obtrusive the overlap

between PRF ANDRO scale items and the PRF scales from which they were drawn originally.

Differences between the four sex role groups, based on univariate analyses of variance computed for the sexes separately, are shown in Table 3. The PRF components are presented in order of decreasing intergroup differentiation.

Although the F ratios in 9 of the 10 rows of Table 3 reveal highly significant differences between groups, it is apparent that these differences are especially pronounced on the first two dimensions, Dependency and Social Poise. On the Dependency dimension, feminine-typed persons attained very high and masculine-typed persons very low scores; the difference between these two groups reached two standard deviations among women. Differences of this magnitude suggest that the median split procedure whereby these persons

were operationally defined as masculine typed (above the median in Masculinity, below in Femininity) and feminine typed (the reverse pattern) is functionally equivalent to splitting the distribution of Dependency component scores at its median and terming high scorers feminine and low scorers masculine! To assess this equivalence empirically, Androgyny difference scores (Femininity minus Masculinity; cf. Bem, 1974) were correlated with Dependency component scores. The resulting coefficients were .79 for men and .82 for women, suggesting that whenever Masculinity and Femininity scores differ greatly, as in strongly sex-typed persons, one might as well speak of individual differences along a dimension ranging from extreme dependency to extreme autonomy. Although the mean Dependency scores in Table 3 suggest some Gender \times Sex Role differences (e.g., indeterminate and androgynous men appear more dependent

than their female counterparts), the main thrust of these results "identifies" masculine versus feminine typing with variations in Dependency. Note that the two non-sex-typed groups, androgynous and indeterminate, differ from both sex-typed groups but not from each other.

On the Social Poise dimension, on the other hand, the pattern of means was very different. Here, androgynous persons scored much higher than did indeterminate persons, the mean difference between these groups being about $1\frac{1}{2}$ standard deviations. Androgynous individuals also scored significantly higher (and indeterminates lower) than the two sex-typed groups (which did not differ from each other). Since scores on the Social Poise dimension are orthogonal to scores on the Dependency dimension, differences in Social Poise obviously comprise an independent major dimension along which sex role groups vary. Since androgynous persons by definition have high scores on Masculinity and Femininity (whereas indeterminates have low scores), it is not surprising that Androgyny sum scores (Femininity plus Masculinity; cf. Strahan, 1975) should correlate .60 (for men) and .59 (for women) with scores on the Social Poise dimension.

Turning to intergroup differences on the Intellectuality dimension, the patterning of group differences was almost identical to that on Social Poise: Androgynous and indeterminate persons again defined the extremes, and androgynous persons scored significantly higher than at least one (and indeterminates lower than both) of the sex-typed groups. Differences on the Defensiveness dimension were less pronounced but resembled those associated with the Dependency dimension, in that among both sexes the masculine-typed persons were the most, and feminine-typed ones the least, defensive. Finally, differences on the Impulsivity dimension suggest that among women, feminine-typed and androgynous persons show greater impulse control than do masculine-typed and indeterminate persons. These differences did not reach significance among men.

Among college students, four of the five principal components have proven salient in

differentiating the groups. Although the resulting characterizations are technically four dimensional, two main patterns emerged: (a) Masculine-typed persons were the most independent and defensive, whereas feminine-typed persons were the most dependent and least defensive; (b) androgynous individuals were the most socially poised and intellectually oriented, whereas indeterminates were the most socially awkward and unintellectual. (These patterns have been fully cross-validated in samples of psychotherapists and alcoholics; see Berzins, Note 1.)

Broader Issues in Construct Validity

Thus far, this article has involved college students only. To facilitate an appraisal of the validity of the Masculinity and Femininity constructs across a variety of populations varying in age, education, occupation, and clinical status, Figure 1 arrays 18 different samples, representing over 6,000 persons, on both scales. Ten samples contain both men and women. Seven samples were scored from the PRF, 11 from the IDI.

The configuration of groups along the Masculinity (vertical) dimension strikingly corroborates the theoretical definition of Masculinity as an amalgam of social-intellectual ascendancy, autonomy, and risk taking. Policemen, men majoring in accounting, and male dental students showed the highest Masculinity mean scores; clinically depressed women, newlywed women, and women enrolled in a hospital weight-reduction program showed the lowest scores. Analyses conducted *within* groups (e.g., a sample of 1,109 college students) have also revealed interesting variations along the dominant-instrumental dimension. For example, college men who, 10 years from now, expected to make as much money as their classmates had mean Masculinity scores of 16.3; those who expected to make more scored 17.8; and those who expected to make much more scored 19.6, $F(2, 383) = 15.27$, $p < .0001$. The comparable values for college women were 12.7, 14.3, and 16.3, $F(2, 720) = 15.67$, $p < .0001$.

The theoretical alignment of Femininity with themes of nurturance, affiliative-expressive concerns, and self-subordination appears

to be corroborated by the fact that high school, college, and "general population" women showed high scores, whereas most male groups and, among women, gay women and women majoring in accounting scored considerably lower. It is curious, however, that both male and female psychotherapists showed relatively low Femininity (and Masculinity) scores in comparison to their respective gender peers. Perhaps because they are the most highly educated and testwise group sampled, and because their interpretation of some nurturance-related items may have been restricted to psychotherapeutic contexts, these therapists did not describe themselves more extremely on this dimension. Although no sample of unemployed housewives with children—who might be expected to show very high Femininity scores—is presented, analysis of college women's anticipated life-styles disclosed highly significant differences in Femininity scores as a function of the number of children these women anticipated having in their own future families. Women anticipating childless versus one-, two-, three-, and four- (or more) child families showed mean Femininity scores of 15.1, 17.2, 17.7, 18.6, and 18.9, respectively, $F(4, 718) = 17.68$, $p < .0001$. For college men, the corresponding values were 12.3, 15.0, 15.0, 14.6, and 14.7, $F(4, 381) = 3.18$, $p < .01$.

The overall distribution of mean scores in Figure 1 clearly shows that the vast majority of groups in our society are sex typed. If we were to treat the entries in Figure 1 as individuals rather than groups, median splits on both scales would classify 12 of 15 male groups as masculine typed and 11 of 13 female groups as feminine typed. The overall percentage (82%), of course, is much higher than that for individuals *within* any one of the groups. It does emphasize, however, the pervasive and highly significant sex differences on both scales in almost every sample tested to date. Indeed, only the self-designated homosexual volunteers did *not* show significant differences on these scales; both gay men and women emerged as quite high in Masculinity and moderate in Femininity (cf. Heilbrun & Thompson, 1977, for similar findings with the Heilbrun scale).

Figure 1. Distribution of Masculinity and Femininity scores across 18 samples (28 groups). (Account = college students in accounting classes, $n = 105$; Alco = hospitalized Veterans Administration alcoholics, $n = 760$; Coll. 1 and Coll. 2 = college students in introductory psychology classes in 1974-1976 and 1970, $n = 2,547$ and 986 , respectively; Dental = dental school students, $n = 54$; Depres = hospitalized clinically depressed patients, $n = 20$; Gay = homosexual volunteers, $n = 71$; Het-VA = heterogeneous nonschizophrenic Veterans Administration outpatients, $n = 33$; High Sch = high school students, $n = 700$; Hospit = hospitalized nonpsychiatric medical patients, $n = 20$; Newlywed = newlywed couples, $n = 198$; Opiate = civilly committed opiate addicts, $n = 216$; Police = municipal police, $n = 25$; Publ sp = college students in public speaking classes, $n = 166$; Schiz = schizophrenic Veterans Administration outpatients, $n = 20$; Therap = psychotherapists and trainees, $n = 276$; VFW = Veterans of Foreign Wars, $n = 57$; Weight = participants in a hospital weight-reducing program, $n = 54$.)

There are exceptions of clinical interest as well. Male schizophrenic outpatients and alcoholic inpatients, for example, showed markedly "feminine" typing. Within both sexes, psychopathology appears to be associated with normatively low Masculinity scores (e.g.,

clinically depressed female inpatients, heterogeneous nonschizophrenic male outpatients) and, among men but not women, with somewhat elevated Femininity scores. Whereas the problems that male schizophrenics have had with respect to gender identity are documented in the literature (cf. LaTorre, 1976), male alcoholics as a group have seldom been depicted as feminine typed by traditional measures of Masculinity-Femininity. From the present theoretical perspective, however, it is entirely reasonable to expect chronic alcoholics (M age = 43.9 years) to score very low on a dominant-instrumental dimension.

Whereas most of the groups in Figure 1 are relatively homogeneous in age (M ages range from 15.7 for high school students to 49.0 for the Veterans of Foreign Wars), cross-sectional comparisons among age groups in the more heterogeneous samples of men reveal low but significant decreases in Masculinity and/or increases in Femininity scores as age increases. Classification of subjects into the four sex role categories, consequently, should be based on normative considerations of age as well as those concerning education, socioeconomic status, and the degree of psychopathology.

General Discussion

The results suggest that the Masculinity and Femininity subscales of the PRF ANDRO scale are independent, reliable, minimally related to socially desirable responding, substantially related to their respective counterparts in the BSRI, convergent with major personality dimensions, and capable of meaningfully differentiating samples varying in age, socioeconomic status, and psychopathology. The appreciable convergences between the PRF ANDRO scale and the BSRI moreover suggest that experimental studies using the former to classify subjects should yield results similar to, if not identical with, studies using the latter (e.g., Bem, 1975; Bem & Lenney, 1976). Furthermore, the fact that the PRF ANDRO scale can be scored from the PRF answer sheets enables other investigators to reanalyze prior studies in terms of the sex role categories delineated in this study.

Substantively, the construal of Masculinity and Femininity as independent dimensions

rather than as opposites, and the resulting quadripartite classification of sex roles, has afforded a rather comprehensive view of the relation of sex roles to personality dimensions. Although masculine- and feminine-typed persons indeed emerged as opposites on some dimensions (e.g., Dependency, Defensiveness), they were relatively indistinguishable on others. On these other dimensions (e.g., Social Poise, Intellectuality), it was the androgynous and indeterminate persons who emerged as "polar opposites." Had the PRF ANDRO scale been constructed in the traditional manner, that is, by selecting PRF items that showed the largest sex differences in endorsement, it is obvious that neither the personality patterns of androgynous persons nor the sex-role-related differences in Social Poise and Intellectuality would have been detected.

To further appreciate the extent to which the present approach, like that of Bem's, differs from traditional ones, recall that one index of the "validity" of traditional measures has been the point-biserial correlation between gender and a measure of masculinity-femininity; such coefficients often exceed .70 (Constantinople, 1973). By this standard, both the PRF and BSRI scales did not fare very well: In Sample 1, gender correlated $-.38$ and $-.36$ with the PRF and BSRI Masculinity scales and $.45$ and $.47$ with the respective Femininity scales. But although sex differences may characterize both traditional and new measures of sex roles, their presence has little to do with overlapping content domains. For example, in a subset of Sample 2 participants ($n = 682$), the correlations between the (bipolar) Masculinity-Femininity scale of the Omnibus Personality Inventory (Heist & Yonge, 1968) and the PRF Masculinity scale were $.04$ (men), $.08$ (women), and $.30$ (combined); the corresponding coefficients with the PRF Femininity scale were $-.22$, $-.16$, and $-.42$. Apart from the higher coefficients resulting from sex differences in the combined sample, it is clear that our measures share trivial content variance with this traditionally constructed measure. In another sample of 206 male alcoholics, the correlations between the Minnesota Multiphasic Personality Inventory Mf scale and our

Masculinity and Femininity scales were $-.06$ and $.00$, respectively. Since our Masculinity and Femininity scales are independent rather than negatively correlated among both men and women, the pervasive sex differences observed in most groups (cf. Figure 1) are better understood as reflecting the consequences of traditional socialization practices (encouraging boys toward self-definitions thought more desirable in men than in women, vice versa for girls) than the psychometric "rediscovery" of biological gender accomplished by compounding items on which the sexes show differing endorsement frequencies.

The multithematic definitions of our Masculinity and Femininity constructs—contrasting social-intellectual ascendancy, autonomy, and risk taking with nurturance, affiliative-expressive concerns, and self-subordination—were corroborated empirically by the factor analyses of the BSRI and PRF ANDRO scale item pools. The reader should note that the "discovery" of these content themes in no way precludes using these instruments in their present form, nor does it argue for the utility of fractionating the present scales into subscales; all items in both instruments correlated significantly with their respective total scores and are intended to emphasize bandwidth over fidelity. Because of their breadth, however, the Masculinity and Femininity constructs can be amalgamated with related major conceptions in personality and interpersonal theory, for example, Bakan's (1966) distinction between agency and communion as male and female principles that require integration (see also Block, 1973; Carlson, 1971), Jung's (1956) animus/anima dialectic, Parsons and Bales's (1955) conception of instrumental and expressive roles, Leary's (1957) and Carson's (1969) organizing interpersonal behaviors around dominance-submission and love-hate coordinates (cf. Berzins, Welling, & Wetter, Note 7), and even Campbell's (1975) recent discussion of the tensions along a selfishness versus altruism dimension throughout history.

Overall, the definition of psychological androgyny that has emerged from the present study emphasizes a relative balance of masculine- and feminine-typed attributes in the context of high social competence (openness

to interpersonal and intellectual experiences). Block (1973) and others have marshaled evidence in support of the proposition that the attainment of higher levels of moral development is coextensive with the integration of traditionally masculine and feminine domains of self-definition and behavior. Conversely, individuals who are neither androgynous nor sex typed—indeterminate persons—are characterized by lower levels of social competence in this study and low self-esteem in others (e.g., Spence et al., 1975; Welling, 1976; Wetter, Note 3).

Finally, the quadripartite classification of sex roles, insofar as it converges conceptually and empirically with the dimensions of the interpersonal behavior circle (Carson, 1969; Leary, 1957; Berzins et al., Note 7) requires examination in the context of interpersonal communication, compatibility, and influence, especially in psychotherapy (Berzins, in press). Even though most therapists are men and most patients women, little research has been devoted to the appraisal of the conditions under which gender- and sex-role matching variables affect the processes and outcomes of psychotherapy. The ascendancy of psychological androgyny as a model of mental health suggests that such research has high priority.

Sensation Seeking in England and America: Cross-cultural, Age, and Sex Comparisons

Marvin Zuckerman
University of Delaware

Sybil Eysenck and H. J. Eysenck
Institute of Psychiatry, University of London

This study compared the factor structure of the Sensation-Seeking Scale (SSS) in English and American samples, and a new form of the SSS, applicable to both samples, was constructed. Three of the four factors showed good cross-national and cross-sex reliability. English and American males did not differ on the total SSS score, but American females scored higher than English females. Males in both countries scored higher than females on the total SSS score and on the Thrill and Adventure-Seeking and Disinhibition subscales. Significant age declines occurred for both sexes, particularly on Thrill and Adventure Seeking and Disinhibition.

The Sensation-Seeking Scale (SSS) was developed in an attempt to provide an operational measure of the construct *optimal level of stimulation* (OLS). The construct is an old one, first formulated by Wundt (1873) to explain the curvilinear relationship between affective reactions and intensities of stimulation. After lying dormant for about 80 years, the OLS resurfaced in the 1950s and early 1960s in many theories, including those of Berlyne (1960), Fiske and Maddi (1961), Hebb (1955), Leuba (1955), Malmö (1959), McClelland, Atkinson, Clark, and Lowell (1953), and Schlosberg (1954). Berlyne, Fiske and Maddi, and Hebb, Malmö, and Schlosberg suggested that the idea of an optimal level of arousal (OLA) could be substituted for OLS, since the arousal construct could accommodate stimulus parameters such as novelty versus constancy, and complexity.

The first SSS (SSS II; Zuckerman, Kolin, Price, & Zoob, 1964) was developed with the idea of predicting responses to the experimen-

tal situation of sensory deprivation. It consisted of a General scale derived from factor analyses of many diverse kinds of items reflecting a positive reaction to or desire for stimulating, exciting, and novel kinds of experiences. This scale was rather heavily loaded with the risk-taking kind of items that subsequently became part of the Thrill and Adventure-Seeking subscale.

The SSS II was initially applied in sensory deprivation experiments, and the idea of stable individual differences in OLS and OLA became the central postulate in the theory developed by Zuckerman (1969) to explain differences in reactions to sensory deprivation. In the late 1960s, interest shifted from sensory deprivation to the broader construct-validity implications of the OLS-OLA measure (Zuckerman, Bone, Neary, Mangelsdorff, & Brustman, 1972; Zuckerman & Link, 1968). The SSS proved to have considerable validity for a variety of phenomena, ranging from design preferences to sexual and drug experiences and volunteering for unusual experiments or risky activities. Most of the research has been summarized in chapters by Zuckerman (1974, in press).

Studies by Farley (1967) and Zuckerman and Link (1968) suggested that there might be more than one factor of sensation seeking, and factor analyses were used in an attempt

The authors gratefully acknowledge the assistance of Judy Kasriel, who obtained the tests from the twins; Violet Beevers, who processed the data for the computer; and the subjects on both sides of the Atlantic who gave us their time and self-reports.

Requests for reprints should be sent to Marvin Zuckerman, Department of Psychology, University of Delaware, Newark, Delaware 19711.

to discover what these factors might be. Zuckerman (1971) reported the "dimensions of sensation seeking" found in samples of male and female undergraduates in the Philadelphia area. Four factors were identified, and three of them showed good reliability in their loadings across the sexes. The fourth factor, Boredom Susceptibility, was not clearly defined in the female group.

The first factor was called *Thrill and Adventure Seeking* (TAS), and it contained items expressing a desire to engage in sports or other activities involving speed or danger. The second factor was called *Experience Seeking* (ES), and it represented the seeking of experience through the mind and senses, travel, and a nonconforming life-style. The third factor was labeled *Disinhibition* (Dis), which seemed to represent the desire for social and sexual disinhibition as expressed in social drinking, partying, and variety in sexual partners. The fourth factor, called *Boredom Susceptibility* (BS), represented an aversion to repetition, routine, and dull people, and restlessness when things are unchanging. Examples of the sensation-seeking parts of the forced-choice items can be seen in Table 2.

Recently, Stewart and MacGriffith (1975) factor analyzed Form IV of the SSS, using 156 American undergraduates as subjects. The authors did not analyze male and female data separately. They found factors corresponding to TAS, ES, and BS, but Dis did not emerge as one of the first four factors. The authors noted that four factors only accounted for a quarter of the total variance and suggested that with no clear basis for only examining four factors, a general scale might suffice. Only four factors were analyzed in the study by Zuckerman (1971) because only four showed some reliable resemblance between the male and female samples. Stewart and MacGriffith suggested that different factors might exist in males and females. This is a possibility, of course, but Zuckerman was looking for factors that had broad applicability. Although the factor scales in Form IV remained substantially correlated, the General scale could not be used as an adequate substitute for the factor scales for two reasons: (a) Since it was based only on items that were contained in the Experimental Form I, it did not include

an adequate sampling of items from several factors based on new items written for Experimental Form III. (b) In the validity studies all of the scales, including the General scale, related to some of the validity criteria, but for other criteria, such as the physiological, only specific subscales showed significant relationships.

Before the Stewart and MacGriffith study, two factor studies were done on Form II of the SSS: one on an English sample (Farley, 1967) and one with a Japanese translation given to a Japanese sample (Ohkubo, Note 1). The general factor, defined by the unrotated factor loadings on the first factor, correlated .67 between English and American samples but only .35 between both American and English samples and the Japanese sample. A translated questionnaire cannot be expected to show very high cross-cultural factor reliability because of language and cultural differences. The reasonably high correlation between English and American samples was encouraging.

One of the aims of the present study was to examine the cross-cultural reliabilities of the factors in Form IV of the SSS, comparing the factor-analytic results from the original study (Zuckerman, 1971) with those from a large, socially heterogeneous sample of an English population. If the four factors originally derived from the American sample were meaningful and had a biological basis (Zuckerman, 1974), they would show cross-cultural as well as cross-sex stability.

A second purpose was to develop a shorter form of the SSS, based on the four factor analyses (English and American males and females). In this form, a total score, derived from the summation of the four factor scores, could be substituted for the General scale in Forms II and IV, which did not contain an adequate sample of items from the Dis and BS factors.

Assuming that the same factors could be found in English and American samples, the third question concerned cultural differences in scores on the sensation-seeking scales. Ohkubo (Note 1) found that both Japanese and Thai students (Thai data from Berkowitz, 1967) scored lower than American students on the General scale of Form II. These

differences must be interpreted cautiously, since they were based on translated sensation-seeking scales. Farley and Farley (1967) found that a sample of English male industrial apprentices and civil servants scored very close to the mean for American college males, despite the differences in socioeconomic and educational levels. The question remains: Do English and American subjects resemble each other on new subscales developed on the basis of factor similarity between the national samples?

Sex differences have been found on the General scale in American, Japanese, and Thai samples and on the factor scales in American college samples (Zuckerman, 1974, in press). A fourth purpose of the study was to see if similar sex differences would be found in the English sample.

A number of studies summarized by Zuckerman (1974, in press) have reported negative correlations between age and the sensation-seeking General scale when the samples covered a wide age range. However, none of these studies have studied age decline in a systematic fashion in all of the sensation-seeking scales. A fifth aim of this study was to examine age decline in the SSS subscales in the English sample. Adequate data are not yet available to do this kind of analysis in an American sample.

Method

Subjects

The English subjects consisted of 254 males and 693 females from the Maudsley Twin Register, ranging in age from 16 to 70. These subjects were used for the following reasons: (a) This group could provide data for a genetic analysis of the SSS; (b) they had previously taken the Eysenck Personality Questionnaire (EPQ) and thus could provide comparison data on these two instruments; (c) they covered a wide age range, thus providing our first good data for age comparison in a normal population; and (d) they were an interested and cooperative group, having answered previous questionnaires by mail. The SSS Form IV was sent out by mail to twins who had previously taken the EPQ. The return rate was about 80%.

The question can be raised as to whether or not twins are a special population. Previous studies showed that twins from the Maudsley Twin Register have normal patterns of scores on personality tests (Eysenck, 1976).

After the data from Form IV were analyzed in the English sample, a new form (Form V) of 40 items was constructed. This form, along with the EPQ, was given to 97 male and female undergraduates from two large sections of undergraduate psychology at the University of Delaware. Most of these students fell in the age range of 17-25, and the modal range was 18-20. The SSS was given first, and the EPQ was given second.

The 72-item SSS Form IV item responses were intercorrelated and factor analyzed in the English male and female samples separately. They were rotated obliquely to simple structure using the promax method, and the loadings were compared with the loadings from the previous study by Zuckerman (1971). Product-moment correlations, the principal components method, and oblique rotations were used in both studies. The previous study (Zuckerman, 1971) factored the SSS Experimental Form III, which contained 113 items, whereas the current study factored Form IV, containing 72 items. The factor structure might have shown some differences due to the extra 41 items in the previous study. These 41 items were not included in Form IV because they showed no loadings of any size on the four primary factors. This means that they contributed little to the interpreted factor structure, so the difference between the two forms should not have introduced much distortion in the comparison of factors across samples.

The sample on which the American factor analysis was based consisted of 160 male and 172 female undergraduates from psychology courses at Temple University. The English sample was much more heterogeneous as to age and education, and differences in the factor structure could have occurred because of the difference in populations. But to repeat the argument used in regard to sex differences in factor structure: If factors are meaningful and have some biological basis, they should be generalizable to a broad range of the population.

Our design allowed for sex and national comparisons of factor reliability: English males with American males, English females with American females, English males with English females, American males with American females, English males with American females, and English females with American males.

Results

Factor Reliabilities

The rotated factor loadings on the first four factors in the six samples were correlated over 71 items. One item from the General scale was missing in the 113-item Form III given to the American groups, but this was not an item contained in any of the factor scales. The matrix of correlations was 16×16 (4 samples \times 4 factors).

The factor reliability coefficients from this matrix are shown in Table 1, which also gives

Table 1
Factor Reliability Coefficients

Comparisons between	Sensation-Seeking Scale factors			
	TAS	ES	Dis	BS
Eng M/Eng F	.90	.68	.79	.70
Eng M/U.S. M	.87	.72	.60	.37
Eng M/U.S. F	.67	.51	.66	.51
Eng F/U.S. M	.88	.68	.66	.65
Eng F/U.S. F	.72	.75	.77	.30
U.S. M/U.S. F	.73	.67	.79	.01
Range of cross-factor correlations	.06 to -.55	.09 to -.49	.41 to -.49	.44 to -.55

Note. Eng = English, U.S. = American, M = males, F = females; TAS = Thrill and Adventure Seeking, ES = Experience Seeking, Dis = Disinhibition, BS = Boredom Susceptibility.

the range of other correlations between different factors within a sample and between different factors across samples. As in the multimethod-multitrait validity model (Campbell & Fiske, 1959), the correlations between the same factors across samples should be significant and exceed the correlations between different factors (traits in the multimethod-multitrait model). Of course, reliability coefficients should also be high as well as being significant.

Three of the four factors clearly met these criteria of factor reliability. Thrill and Adventure Seeking, Experience Seeking, and Disinhibition all showed significant and reasonably high resemblance between the four national and sex samples. With the exception of only 1 of the 18 correlations for these three scales, the coefficients all exceeded .60 and all fell above the range of the cross-factor correlations.

The case was not as clear for the Boredom Susceptibility factor. Although the factor was fairly similar in English males and females, it showed no correspondence in American males and females, and two of the four cross-national comparisons showed weak ($< .40$), if significant, resemblance. Only three of the coefficients exceeded the range of the cross-factor correlations for this factor.

Construction of Form V

On the basis of the four factor analyses, an attempt was made to select items for a new

form (Form V), with the aim of using 10 items for each factor that met the criteria of having a primary loading on the same factor in all samples and loadings exceeding .30 in magnitude. Such scales would have the greatest value for the cross-cultural comparisons.

There was no problem in meeting these criteria for TAS, in which all but one of the items (21) had loadings over .30 on the factor in all four samples. When a choice had to be made between items having similarly high factor loadings, an attempt was made to diversify the content in the new scales.

For Dis, one item (47) had to be selected that did not meet the criteria in the American male sample and another (66) that did not in the English male sample. The BS scale had previously been defined by male loadings, since the factor was not well defined in the American females. Another item (12) did not meet the criteria in the English males. One item (61) had to be included even though it did not meet the criteria in the American analyses. The most radical change was on the ES scale, on which three new items (11, 15, and 25) had to be included even though they did not meet the criteria in all the samples. In some cases items with loadings of slightly less than .30 had to be used, but they always had their highest loading on the relevant factor.

In this manner, 10 items were selected from each of the four primary factors in the SSS to comprise Form V. A total score for this new form can be obtained by summing the

four subscale scores, but Form V contains no general scale as did Form IV.

Table 2 shows the sensation-seeking choice on each item selected, with the factor loadings of that item on the appropriate factor in each of the four samples. In comparing these loadings it should be remembered that the factor analyses were of 72 items in the English sample and 113 in the American sample, so that some of the total variance may have been on items not directly compared across samples.

Scale Reliabilities on Forms IV and V

Table 3 shows internal reliabilities in the English and American Temple University samples for Form IV and the English and American University of Delaware samples for Form V. The reliabilities of the English and American samples were quite similar for Form IV even though the structure of these scales was determined only by the American factor analyses.

The reliabilities of the Form V factor scales were expected to be somewhat lower because the scales were shorter, that is, 10-item scales as opposed to 14- and 18-item scales in Form IV. Actually the only substantial drop in reliability was on the ES scale where reliabilities fell from .7 and .8 to .6.

The most homogeneous scales, TAS and Dis, showed little loss of reliability in the new form; the ES reliability fell somewhat but was still within acceptable limits; the BS reliability remained at the borderline range of high .5, where it had been for American females in Form IV.

Correlations Between Scales

The correlations between the factor scales in Forms IV and V are shown in Table 4. These scale correlations had been rather high in Form IV, and it was hoped that the scales in Form V would have more independence, although some significant correlation was still expected.

Table 4 shows that the correlations among subscales, particularly among ES, Dis, and BS, that were quite high in Form IV were reduced in Form V. TAS continued to correlate with ES in Form IV but showed very low and

sometimes insignificant correlations with Dis and BS.

National and Sex Differences

Table 5 shows the comparisons of English and American male and female samples on Form V. Form V was felt to be most appropriate for these comparisons, since these factor scales were based on cross-national similarity of factors. Only the 16- to 19-year-old English subjects were used in these comparisons, since the American college students were mostly within this age range. Although the young English and American males were not different on the total SSS score, the American males were significantly higher on Experience Seeking, and the English males scored higher on Boredom Susceptibility. The American females were significantly higher than the English on the total score, the Thrill and Adventure-Seeking scale, and the Experience-Seeking scale.

Looking at sex differences within the two national groups, both English and American males were significantly higher than the females on the total score and on the TAS and Dis factor scores. The English males were higher than the English females on BS. There were no significant sex differences on the ES scale in either country.

Age Comparisons

Table 6 shows the mean scores of the males and females on the SSS, Form V within each age group of the English sample. Figure 1

Figure 1. Changes in sensation-seeking total scores as a function of age. (SSSV = Sensation-Seeking Scale Form V.)

Table 2

Loadings of Items Selected for Form V of the Sensation-Seeking Scale

No. on Form IV	Item	Loading			
		English		American	
		M	F	M	F
Thrill and Adventure Seeking					
10	I often wish I could be a mountain climber.	.68	.47	.44	.31
21	I sometimes like to do things that are a little frightening.	.43	.36	.50	.25
29	I would like to take up the sport of water skiing.	.62	.73	.71	.64
31	I would like to try surfboard riding.	.64	.64	.76	.56
35	I would like to learn to fly an airplane.	.45	.64	.63	.33
37	I would like to go scuba diving.	.59	.58	.64	.36
43	I would like to try parachute jumping.	.63	.69	.66	.32
53	I like to dive off the high board.	.53	.54	.54	.45
69	I would like to sail a long distance in a small but sea-worthy sailing craft.	.52	.46	.54	.38
71	I think I would enjoy the sensations of skiing very fast down a high mountain slope.	.65	.58	.57	.52
Experience Seeking					
11	I like some of the earthy body smells.	.40	.39	.46	.16
15	I like to explore a strange city or section of town myself, even if it means getting lost.	.28	.56	.23	.48

61	I like people who are sharp and witty even if they do sometimes insult others.	.47	.29	.25	.05	
70	I have no patience with dull or boring persons.	.54	.37	.32	.39	

Note. M = male, F = female. Only the sensation-seeking choices in the forced-choice items are presented here; a copy of Form V can be obtained from the first author.

shows the data for the total score, and Figure 2 shows the trends for the separate scales.

The *F* values from simple analyses of variance between the age groups for each sex are shown in Table 6. The age differences in sensation seeking were significant for the total score and on all scales for the females. The age change was significant for the total score and the Thrill and Adventure-Seeking and Disinhibition scales for males but was not significant for Experience Seeking and Boredom Susceptibility. Examining Figure 2, it is apparent that the fall in SSS scores was more pronounced for the TAS and Dis scales than for the ES and BS scales.

Discussion

Considering the differences in populations sampled in England and America and the additional items used in Form III on the American sample, the amount of cross-national and cross-sex correspondence in the SSS factors is impressive. Even the Boredom Susceptibility factor, which had not shown cross-sex reliability in the American sample, did show such reliability in the English one. The data argue strongly for the meaningfulness of the factor

scales of the SSS Form IV. This is not to say that we can generalize to other cultures. The status of the factors in translated forms of the SSS is still an open question.

On the basis of the factor stabilities, we were able to construct a new shorter Form V of the SSS, with a total score balanced for the four factors. This new form has the advantage of reducing the interscale correlations between component factor scores with little loss in reliability of these scores. Form V should prove useful in further research on sensation seeking on both sides of the Atlantic.

Although there were educational differences between the younger American and English samples that were compared, education has not proved to be a highly significant factor in the SSS (Farley & Farley, 1967; Kish & Busse, 1968). The English and American males did not differ on the total score on Form V, but the pattern on the subscales was different, with Americans scoring higher on Experience Seeking and the English scoring higher on Boredom Susceptibility. Experience seeking seems to represent a style of life common in the 1960s that is still an influence in America in the 1970s but it is apparently not as important in England. The ES scale was

Total scores (Form V)	—	—	—	—	.83	.86	.84	.85

Note. M = males, F = females; TAS = Thrill and Adventure Seeking, ES = Experience Seeking, Dis = Disinhibition, BS = Boredom Susceptibility. All coefficients in the table are significant, $p < .01$.

^a Alpha coefficients were used; $ns = 254$ males and 693 females.

^b Split-half corrected coefficients were used; $ns = 160$ males and 170 females.

^c Internal consistency coefficients (from interitem rs) were used; $ns = 97$ males and 122 females.

the only one that did not show any hereditary influence in the preliminary study by Buchsbaum as reported in Zuckerman (1974). Experience seeking may have been most influenced by the educational differences between the two samples.

Disinhibition seemed to be less influenced by cultural differences than did other scales. Some unpublished data on racial differences in America (Kurtz & Zuckerman, Note 2) have shown that blacks are lower than whites on

TAS and BS but not on Dis or ES. Dis seems to be the most culture-free scale, and it is the one most highly related to certain psychophysiological variables (Zuckerman, 1974).

In contrast with the males, the American females were significantly higher than the English females on the total score and on the ES and TAS subscales. As with the males, no national differences were found on the Dis scale.

The new Form V shows more selective sex

differences than does the old Form IV, on which males were higher than females on all of the scales (Zuckerman, 1974). On Form V the replicated (across nations) sex differences were limited to the TAS and Dis scales. Males also scored significantly higher on the total score in both countries. The Dis scale showed the largest sex difference, even on Form IV. The difference on Dis can, of course, be interpreted as reflecting different kinds of socialization experiences of males and females in

both countries. However, the finding of a relation between gonadal hormones and Dis in a sample of American males (Daitzman, Zuckerman, Sammelwitz, & Venkateshu, Note 3) suggests that biological factors may also play a role in differences on this personality dimension.

The decline in sensation seeking with age was predicted in the theory formulated by Zuckerman (1969). In the chapter by Zuckerman (1974), it was predicted that TAS and

Figure 2. Changes in sensation-seeking subscale scores as a function of age. (SSSV = Sensation-Seeking Scale Form V.)

ES would decline at faster rates than Dis and BS. The results showed a greater decline for TAS and Dis than for ES and BS. A regression analysis showed that age accounted for 18% of the variance for Dis, 21% for TAS, 5% for ES, and 3% for BS. There was a clear linear decrease in sensation seeking with age on the total SSS score.

What is the basis of the increasing cautiousness and conservatism of age? It might simply reflect the mellowing effect of accumulated experience. But many biological changes also occur with age, including a slowing of cortical activity and diminution of gonadal hormone output. Eysenck (1967) has suggested that biological factors may affect attitudinal traits. It can be hypothesized that the same biological factors that are prominent in aging affect the sensation-seeking tendency.

The other part of the age postulate (Zuckerman, 1969) suggests that sensation seeking increases from childhood to adolescence. Farley and Cox (1971) found no increase from ages 14 to 17. A new instrument will have to be developed for younger children in order to test this hypothesis.

Validation of the Beck Depression Inventory in a University Population Using Psychiatric Estimate as the Criterion

William Bumberry and J. M. Oliver
Saint Louis University

James N. McClure
Washington University

This study investigated the utility of the Beck Depression Inventory for survey use in a college population by determining its concurrent validity, using psychiatric rating of depth of depression as the criterion ($N = 56$). Interrater reliability of psychiatric estimate as measured by a Pearson product-moment correlation coefficient was .62, perhaps because the primary and secondary raters used different diagnostic procedures. The Pearson product-moment correlation coefficient between the inventory and the psychiatric rating was .77. These findings indicate that the Beck Depression Inventory is indeed a valid instrument for use in a college population. The Pearson product-moment correlation coefficient between the inventory and the psychiatric estimate fell to .30 in a second sample in which 1-14 days intervened between administration of the inventory and the psychiatric interview ($n = 27$). This attenuation in subjects who experienced a time delay is consistent with the nature of the depression inventory as a measure of state as opposed to trait depression. The apparent decline in measured depression additionally suggests the need for longitudinal study to determine its course and outcome.

Depression is widely viewed as the most frequently occurring psychic disorder among college students. Seligman (1973) contends that it is not only the most common of the psychological dysfunctions among students, but it is also increasing in frequency. Very little information is available concerning the prevalence of depression in college populations.

Recently, however, Oliver, Croghan, and Katz (Note 1) have estimated the prevalence of depression in college students by administering the Beck Depression Inventory (Beck, 1970; Beck, Ward, Mendelson, Mock, & Erbaugh, 1961) to a random sample of freshmen and sophomores at four private, medium-

sized, coeducational, urban universities. When the criterion for depression was set at a number or intensity of symptoms associated with a diagnosis of depression in a psychiatric population, 23% of the respondents qualified as at least mildly depressed. These findings suggest that the rate of depression may be as much as 50% higher in college students than in American adults between the ages of 18 and 74, in whom the prevalence of depression was cited as 15% in a special report on depression issued by the National Institute of Mental Health (1973). Thus, there is a large discrepancy between the estimates of the rate prevailing in the unselected population reported by the National Institute of Mental Health and that found by Oliver et al. using the Beck Depression Inventory.

The Beck Depression Inventory is a clinically derived self-report inventory of depression designed for use in psychiatric populations. It was constructed to assess the current depth of depression, whether or not depres-

The completion of this study was made possible by the generous participation of James Halikas and Amos Weiner, both of Washington University Medical School.

Requests for reprints should be sent to William Bumberry, who is now at 1970 Latham, Apartment 44, Mountain View, California 94040.

sion is viewed as the primary diagnosis, and consists of 21 items covering affective, cognitive, motivational, and physiological areas of depressive symptomatology. The range of possible scores extends from 0 to 63, with scores of 0-9 being categorized by Beck as not depressed, 10-15 as mildly depressed, 16-23 as moderately depressed, and 24-63 as severely depressed.

Two validation studies were reported by Beck et al. (1961); they were conducted in psychiatric populations, with psychiatric assessment of depth of depression comprising the criterion measure with which the depression inventory was compared. Biserial correlation coefficients of .65 and .67 were obtained ($ns = 226$ and 183 , respectively). These validation studies may be largely responsible for the rather widespread application that the depression inventory has recently enjoyed, having already been used as a criterion measure in well over 100 published studies (Beck & Beck, 1972). In spite of its popularity, however, it should be noted that the depression inventory was designed for use with psychiatric populations and has not been demonstrated to be a valid measure of depression for survey use in a college or any other unselected population.

The purpose of this study was to assess the applicability of the Beck Depression Inventory for survey use in this population. The method consisted of determination of the concurrent or diagnostic validity of the depression inventory, using psychiatric rating of depth of depression as the criterion measure.

Method

Subjects

Subjects in this study consisted of 56 university students (27 males and 29 females) at both undergraduate and graduate levels from two medium-sized, private, coeducational, urban universities (Washington University and Saint Louis University) located in the same midwestern city. The Scholastic Aptitude Test scores at these two institutions averaged 550 Verbal, 590 Math and 500 Verbal, 500 Math, respectively.

An attempt was made (although unsuccessfully) to include an equal number of subjects from each of the four categories of depression as designated by Beck. Since 77% and 16% of randomly selected

lowerclassmen can be expected to score in Beck's normal and mild categories, respectively (Oliver et al., Note 1), subjects in these two categories ($ns = 16$ and 19 , respectively) were obtained through a random sampling procedure at Saint Louis University. The university phone directory, constituting the registrar's list, provided the pool from which subjects were randomly selected. Each subject from this pool was personally contacted.

Since only 6% and 1% of randomly sampled lower classmen can be expected to fall in the moderately and severely depressed categories, respectively, this strategy had to be supplemented to procure a sufficient number of subjects in these categories ($ns = 17$ and 4 , respectively). More extensive sampling was obtained by administering the depression inventory to various large undergraduate and graduate classes. Finally, with the cooperation of the psychiatric division of the Samuel B. Grant Health Service at Washington University, students referred for psychiatric evaluation with and without depression were referred to the study. These subjects were administered both the depression inventory and the psychiatric interview for depth of depression before any other diagnostic or therapeutic procedures were introduced.

Materials

The Beck Depression Inventory as originally published (Beck et al., 1961) was used. After the subjects had completed the entire inventory, the duration of each symptom was also obtained.

The structured interview used by the primary psychiatrist was developed and has been used for over 2 decades by the Washington University Department of Psychiatry. Interrater reliability of information derived from this interview has been discussed by several investigators (Feighner, Robins, Guze, Woodruff, Winokur, & Munoz, 1972; Helzer et al. 1977). Data obtained from this interview form the basis of the forthcoming revision of the *APA Diagnostic and Statistical Manual* (APA, in press) and of numerous publications concerning a wide range of disorders from anxiety neurosis to organic brain syndrome and including depression.

Those psychiatrists providing estimates for the purpose of assessing interrater reliability, however, did not use this structured interview but proceeded with a diagnostic clinical interview however they saw fit.

Procedure

Requirements for participation in the study were briefly explained, informed consent was obtained, and confidentiality was promised. The inventory was then administered to all subjects, either individually to those students randomly sampled, in a group for the large classes, or self-administered to students referred from the Health Service, before subjects participated in a psychiatric interview.

Table 1
Percentages of Interrater Pairs of Psychiatric Ratings as a Function of Degree of Agreement Between Psychiatrists

Degree of agreement	Beck (1970)	Current study
Complete	56	61.5
1 degree of disparity	41	38.5
2 degrees of disparity	2	0
3 degrees of disparity	1	0

Note. The data in column 1 are from *Depression: Causes and treatment* (1st ed.) by Aaron T. Beck, 1970, p. 194. Copyright 1967 by Aaron T. Beck. Reprinted by permission.

Subjects were selected for participation in the psychiatric interview according to depth of depression as measured by the depression inventory, but all interviews were conducted by interviewers blind to depression inventory scores. Structured interviews as described above were conducted to assess the current depth of depression, scored in four levels as none, mild, moderate, or severe according to the criteria developed by Beck for his validation studies (Beck et al., 1961). The interviews were conducted by a board-certified psychiatrist (the third author) with 20 years of experience who maintains both a student practice through the Health Service and an adult practice.

Measures of interrater reliability were obtained at the beginning and end of the study. Both measures were obtained by comparing the primary ratings with those made by one of two additional board-certified psychiatrists, the first (J.H.) with 9 years of clinical experience and the second (A.W.) with 4.

Results

Interrater reliability between the primary psychiatrist providing criterion ratings for depth of depression and the two other psychiatrists, as measured by a Pearson product-moment correlation coefficient, was .62. The proportion of pairs of psychiatric ratings manifesting varying degrees of agreement between psychiatrists, from complete agreement through complete disagreement across the four levels of depression, obtained in the present study and those reported by Beck (1970) are presented in Table 1 for the purposes of comparison.

The Pearson product-moment correlation coefficient between the scores on the depression inventory and the primary psychiatrist's

ratings of depth of depression, with no depression scored as 0, mild as 1, moderate as 2, and severe as 3, was .77 ($SE = .14$, $p < .001$).

For purposes of comparison with Beck's original validation data, the Pearson biserial correlation coefficient was calculated on the same data, after reducing the number of criterion categories from four to two, normal and mild as opposed to moderate and severe. The corresponding coefficient was .79 ($SE = .17$, $p < .001$). Figures summarizing the relationship found in the present study together with those originally reported by Beck (1970) are provided in Table 2.

The dichotomizing of psychiatric ratings for the purpose of calculating a Pearson biserial correlation coefficient produced a rather large disparity between numbers of subjects in the normal and mild category on the one hand and the moderate and severe category on the other. In this case, therefore, this statistic unfortunately yields a large standard error of .17. In the treatment of data originating in this study then, the product-moment correlation, with its smaller standard error, is preferred.

There was no significant association between psychiatric rating of depth of depression and either sex, $\chi^2(3) = .95$, $p = .81$, or grade level, $\chi^2(3) = .85$, $p = .84$.

gories of psychiatric ratings of depth of depression are furnished in Table 3.

Use of Beck's recommended cutting point of 10 between normal and depressed scores resulted in 2 false positives and 7 false negatives ($p = .18$), whereas retention of his suggested category boundaries produced 27 cases that were inaccurately categorized, of which 15 were overestimates and 12 were underestimates ($p = .70$).

A second, smaller sample ($n = 27$) was run consisting of cases in which a time interval ranging from 1 to 14 days intervened between administration of the depression inventory and psychiatric interview. The Pearson product-moment correlation coefficient between inventory score and psychiatric estimate within this second sample with delay was only .30 ($SE = .21$, $p < .05$). The Pearson biserial correlation coefficient for this same second sample was not meaningful, since the standard error was .36.

Discussion

The primary finding of this study is that the Beck Depression Inventory does indeed appear to be a valid instrument for the measurement of depression in a university population when psychiatric estimate of depth of depression is considered to be the standard. The extent of the correlation is, perhaps, a matter of some surprise, since the pencil-and-paper test was devised by Beck to assess depression conceptualized as a heterogeneous collection of dysfunctions while the psychiatric rating was rendered by a psychiatrist who generally endorses an organic approach to depression. This suggests that depression is a phenomenon of sufficient salience and stability to be detected by various approaches to pathology. When the depression inventory is applied solely as a measure of the current state of depression, the proportions of falsely identified cases clearly indicate that the depression inventory is not associated with any systematic tendency to overestimate or underestimate depression.

There was a strong association between depression inventory scores of 15 and above and a positive response to Item I, which requests

Table 3

Beck Depression Inventory Means and Standard Deviations as a Function of Psychiatric Estimate of Depth of Depression

Statistic	Psychiatric estimate of depth of depression			
	Normal	Mild	Moderate	Severe
<i>n</i>	16	19	17	4
<i>M</i>	3.94	14.10	22.18	19.50
<i>SD</i>	4.46	5.99	8.19	7.55

Note. $n = 56$

information on thoughts of suicide, $\chi^2(1) = 33.65$, $p < .001$, suggesting that a score of 15 or more warrants individual attention to this item. Many subjects, not only those rated as severely depressed by psychiatric estimate, responded positively to the self-harm item.

A major difficulty in this study relates to the question of generalizability, since the criterion measure of psychiatric estimate of depth of depression consists of ratings provided by the primary psychiatrist. Clearly, it would have been desirable to have several psychiatrists participating in the study. The obtained measures of interrater reliability were directed toward this issue, with the results at a generally acceptable level. The somewhat modest correlations between pairs of psychiatric ratings perhaps derive from the fact that the primary and secondary psychiatrists used differing interview procedures, the former following a structured format and the latter using personally determined clinical interviews. The marked contrast between the theoretical orientations of the primary rater and the originator of the depression inventory, however, suggests that a similar correlation between the inventory and the psychiatric estimate might well have been obtained had a number of psychiatrists of varying theoretical persuasions been used to provide criterion ratings.

A second deficiency in this investigation was the small number of subjects who were judged as severely depressed by psychiatric estimate. Sampling procedures were designed to identify this portion of the population, but unfortunately an adequate number was not secured.

The peculiar reversal of the size of the mean scores on the depression inventory between the groups judged moderate and severe by psychiatric estimate shown in Table 3, with the mean for the moderate exceeding that of the severe category, suggests that both the depression inventory and the psychiatric ratings could be invalid at higher levels of depression. The small number of subjects in the severe range, however, indicates that this effect may be attributable only to errors in sampling and precludes drawing further inferences. This remains a question for further study.

The relatively small number of subjects in the moderate and severe categories combined provided little data relevant to the typically reported finding of a significantly higher proportion of females than males undergoing depressions of clinical significance. According to this sample, undetected depressive episodes occurring in the unselected university population are equally likely to afflict both males and females.

The remarkable accuracy of prediction of psychiatric estimate of depth of depression by the depression inventory when psychiatric interview is administered on the same day as the inventory indicates that the inventory elicits little error variance when psychiatric rating is accepted as the criterion. Since in a significant majority of the cases comprising the second sample with time delay (20 out of 27, $p < .025$), the psychiatric rating placed the subject in a milder category of depression than did the depression inventory, it may be inferred from the accuracy of the instrument that in this subsample the depression inventory scores had declined during the intervening time period. This apparent tendency of depression inventory scores to diminish over the passage of time may reflect either spontaneous remission or the subject's attempt to present a more favorable impression during the second assessment.

With a view toward providing a measure of the "steady state," the duration of each symptom of depression that was acknowledged was obtained, with responses scored 1-4 for less than 2 weeks, 2 weeks to less than 6 months, 6 months to any number of years,

and "always," respectively. These duration scores were used as weights by which the item or symptom scores were cross-multiplied, and the total of cross-products provide a composite score representing both severity and duration of depression. It was anticipated that this composite score might not only indicate those subjects who had been depressed but might also predict those who would remain depressed. Though composite scores reflecting self-reported duration correlated very highly with depression inventory scores ($r = .94$, $p < .0001$), they proved less accurate than the "current state" scores as predictors of psychiatric estimate of depth of depression ($r = .40$, $p < .01$). These findings indicate that self-reported duration of symptoms does not provide a useful prognostic index about the future course of depression.

Although the self-reported duration of symptoms failed to provide an accurate measure of steady state depression, the low correlation between scores on the depression inventory and the psychiatric rating for subjects for whom a time interval separated administration of the inventory and the interview raises the issue of the degree to which the state measured by the inventory is stable. These findings suggest the need for longitudinal observations of depressed states in this and other general adult populations to determine their course and outcome.

Projective and Repressive Styles of Processing Aversive Information

Alfred B. Heilbrun, Jr.
Emory University

The relationship between projective and repressive styles of dealing with aversive information about the self as well as sex differences in the use of these two defensive styles were studied in normal subjects. An inverse relation between the use of projective attribution and repressive forgetting of negative traits was found independent of sex, supporting the assumption of individual differences in the utilization of the major defense mechanisms. Females used repression more than males, but no sex difference in projection was shown. Implications of these findings for personality theory and research methodology are presented.

Defense mechanisms, the cognitive operations by which people protect themselves from psychological threat, have played a major role in psychodynamic formulations of psychopathology since Freud stressed the centrality of repression (Freud, 1957) and projection (Freud, 1938, 1956) within psychoanalytic theory. A great deal of research has been directed toward verification of repression or projection as clinical constructs or toward the testing of various theories relating to their occurrence or effects. However, reviews of the research literature on repression (Holmes, 1974; Mischel, 1976), the selective forgetting of distressing information, have led to the same pessimistic conclusion. There is little firm evidence for the validity of this construct. The verdict of review concerning the demonstrability of projection as a defense mechanism was somewhat less negative. Holmes (1968) utilized a fourfold typology to consider the research on the attribution of traits to others as a way of denying or otherwise ameliorating the aversive effects of an unacceptable self-characteristic. Was the subject aware of the unacceptable trait or not, and was the attributed trait the same or different from the unacceptable trait? Holmes

concluded that there was no experimental evidence for unconscious projection of unacceptable traits, the classical form of projection proposed by Freud. He did find support for the attribution of traits to others given an awareness of the trait by the individual.

The question remains why it has proven so difficult to develop an impressive backlog of experimental evidence for such popular psychodynamic constructs as repression and projection. The problem may reside in the limitations of theory relevant to the defense mechanisms. It is also possible that the problem is methodological. It is difficult to devise experimental paradigms that are convincing tests of these constructs and that are sufficiently precise so that the results are not vulnerable to alternative explanation.

Yet another possible reason for the equivocal status of repression and projection research is the nature of inference frequently used in such studies. There is a tendency for results to be considered in dichotomous terms; either subjects, considered collectively, demonstrate behavior defined as defensive or they do not. If a sufficient number do not, then the results fail to support the usefulness of the clinical construct. However, defenses as cognitive operations should be expected to occur in varying degrees; for example, some might use repression consistently in dealing with threatening material, others might occa-

Requests for reprints should be sent to Alfred B. Heilbrun, Jr., Department of Psychology, Emory University, Atlanta, Georgia 30322.

sionally engage in repression, and yet others might never deal with threat by using selective forgetting. Furthermore, we might expect individuals to have different hierarchies of defense against threat. One person could be characterized as having a primary repressive style but have other defenses available, whereas another person might maintain primarily a projective style and less frequently deal with threat in other ways.

These observations suggest some methodological innovations in investigating the defense mechanisms. For one, the experimental method should provide the opportunity to assess more than one defensive operation in dealing with the same material. The subject who fails to demonstrate a particular mode of defense (and in previous studies might be thought of as disconfirming that construct) may be shown to be neutralizing threat by a different tactic higher in the hierarchy of defenses. Said another way, this procedure more likely would allow for the demonstration that people have different characteristic styles of dealing with aversive information. Second, the experimental method should allow for the systematic study and analysis of sex differences in characteristic defensive behaviors. The importance of sex differences in ego defense derives first from the fact that they remain virtually unexplored, at least in children (Maccoby & Jacklin, 1974), and, as far as I can discern, in adults as well. If such basic differences exist, it would not only be of some theoretical interest but should be considered in the sampling procedures of subsequent research involving the defense mechanisms.

The present experiment provided subjects with the opportunity to deal with aversive information potentially relevant to themselves by using either a projective or repressive defensive style. No constraints were imposed regarding whether neither, one, or both defenses were used. Two specific issues were investigated. (a) Given the option of either defending against threatening information by projection or repression, will normal subjects tend to use one defensive style and not the other? and (b) Do males and females differ

in the extent to which they use projective and repressive defensive styles?

Method

Subjects

The 47 subjects in this experiment were volunteers from a large undergraduate class at Emory University. Of this number, 30 were males and 17 were females. The mean ages were 18.5 years for the males and 18.3 years for the females.

Measures

The basic instrument from which the evaluative materials were taken for this experiment was the Adjective Check List (Gough & Heilbrun, 1965), a 300-item compilation of behavioral adjectives.

The adjectives on the Adjective Check List have been rated by college students as to their favorability/unfavorability if used to describe a person (Gough, 1955). Seventy-five adjectives have been identified as favorable, 75 as unfavorable, and the remaining 150 adjectives are considered neutral in an evaluative sense. A set of 22 adjectives was selected from each of these three evaluative categories, and these 66 words comprised the critical word list in the present study. Since the projection and repression scores, to be described later, depend on the reliability of these categories, new ratings were obtained from the subjects in this experiment to verify category meanings, since projection and repression scores, to be described later, depend on the reliability of their categories. The mean rating for each evaluative term (given in Table 1) is based on a 7-point scale ranging from highly unfavorable (score = 1) through neutral (neither favorable nor unfavorable—score = 4) to highly favorable (score = 7). Generally speaking, Gough's original groupings held up very well. The favorable and unfavorable categories of evaluative terms, on which both defensive scores were based, provided nonoverlapping values. The rating for each term within these two categories fell on the appropriate qualitative side of the neutral point, and the grand mean rating for the favorable terms (5.84) was over three rating intervals from that for the unfavorable terms (2.46) on a 6-interval scale.

Procedure

Subjects were seen for two sessions. The first was a small group session during which the subjects were asked to rate the favorability or unfavorability of the words comprising the critical word list. These 66 behavioral adjectives were randomly dispersed throughout a rating form made up of 120 adjectives taken from the Adjective Check List. The 54 buffer items were added to reduce a priori familiarity with

Table 1
Favorability Values for Words on the Critical Word List

Qualitative category

tactless	2.04	trusting	5.89	tolerant	5.45
undependable	1.72	uninhibited	4.83	understanding	6.34
weak	1.94	wary	4.19	warm	6.17

Note. Mean ratings are based on $N = 47$; values range from highly unfavorable (1) to highly favorable (7). The qualitative category is based on Gough's original groupings.

the critical words to be subsequently used in memory tasks.

Subjects were then seen individually in a laboratory session within approximately the next week. During the initial part of the laboratory session, the subject was told that a series of words taken from a survey of mothers who had been asked to describe their college-age children was going to be presented. The subject was instructed to listen carefully and to remember as many of the words on the list as possible. These instructions regarding maternal evaluation, while not made specific to the subject in question because of ethical constraints (i.e., they were not offered as what the subject's mother thought of him or her), have proven successful in creating an evaluative set in several previous studies by me. I (Heilbrun, 1973a) have reviewed these studies elsewhere. The taped list presented the words in repeating triads of favorable, unfavorable, and neutral. The words were spoken in an adult female voice at 5-sec intervals and were presented at a clearly audible volume. Earphones were provided to preclude irrelevant auditory stimulation.

As soon as the final word had been presented, the subject was given a copy of the Adjective Check List and was asked to check those words that had

appeared on the list. The subject was informed that there were 66 words on the list and that exactly that number was to be checked even if it required guessing. Once this was done, the female graduate student experimenter offered the following instructions:

Some of the words used to describe college-age sons (daughters) may be descriptive of you, and some may not. I want you to go through the words you checked and indicate for each one whether you feel it is more descriptive of you than of most college males (females) or whether it is more descriptive of most college males (females) than it is of you.

Subjects then went through the 66 checked words and indicated by using different colored pencils (with a color code continuously available) which of these two alternatives obtained for each term.

Sent to a room down the hall, the subject was met by a second experimenter. This male graduate student administered a filler questionnaire to occupy the subject's time during the next 30 minutes. When the questionnaire had been completed or 25 minutes had elapsed (whichever came first), the subject was told to return to the original room and wait outside in the chair until recalled by the female experi-

menter. This experimenter recalled the subject after exactly 30 minutes had elapsed from the time the subject had left her research room. The purposes of this filler period were twofold: (a) to be sure that sufficient time had elapsed since last exposure to the critical words so that subsequent recognition would qualify as long term and (b) to occupy the subject on a distractor task for as much of this time as possible to avoid rehearsal of the terms previously encountered.

The final part of the laboratory session required the subject to again recognize as many of the words heard on the tape from among those on a new Adjective Check List. Exactly 66 check marks were requested. When this was completed, the subject was thanked and was urged not to discuss the experiment with anyone else.

Results

Projection

Projection was estimated from a score that considered the extent to which the subject attributed unfavorable evaluative terms, correctly recognized from the maternal list, to peers rather than to self. The projection term of this score was *the number of correctly recognized unfavorable terms attributed to others minus the number of correctly recognized unfavorable terms attributed to self*. However, this term, taken alone, would not discriminate between the person who denies unfavorable traits and defensively attributes them to others and the competent individual who justifiably rates peers as more adequately described by the unfavorable terms. Accordingly, a correction term (*the number of correctly recognized favorable terms attributed to self minus the number correctly recognized favorable terms attributed to others*) was subtracted from the projection term to compensate for positive self-esteem. The more positive the difference between the projection and correction terms, the more the selective attribution of negative characteristics to others outweighs the selective endorsement of positive characteristics. In other words, the higher scorer is processing potentially self-relevant negative traits in an extraordinary way relative to positive traits and in a style expected of a projector. Lower scores, whatever they mean about the person, clearly contraindicate a processing of negative traits in a projective style.

This projection scoring procedure was used in a previous study in which theoretically predicted relationships between maternal experience and defensive style were obtained (Heilbrun, 1972). More recently, further evidence of the heuristic value for this index of projection was obtained by showing that valid predictions from a projective test (the Thematic Apperception Test) could be made for projectors but not for nonprojectors (Heilbrun, in press).

A comparison between the mean projection score for males (1.63, $SD = 4.60$) and females (3.00, $SD = 4.90$) revealed no statistically significant difference between the two sexes, $t(45) = .94$, $p > .30$. Males and females did not differ in their utilization of a projective style of processing aversive evaluative information.

Repression

The repression score reflected the extent to which the person failed to correctly recognize unfavorable terms from the critical list during the second retention test after correctly recognizing them during the first retention test and attributing them to himself or herself. In other words, at an earlier time the subject had been aware of aversive self-characteristics but subsequently failed to remember them. Unfavorable terms from the critical list assigned as self-characteristic will be referred to as "repression relevant." Two corrections were required within this score before assuming that the failure to recognize repression-relevant words represented a repressive style of processing negative information.

1. The number of repression-relevant words that the person fails to remember during the second retention test should be considered in terms of the original number of such words. The subject who has self-attributed 10 of the mothers' unfavorable terms and forgets 2 of these (80% recognition) is showing less forgetting than the subject who forgets 2 of these terms from an original number of 4 (50% recognition). Accordingly, a percent retention score (number of repression-relevant terms retained divided by total number of repression-relevant terms) was used to correct

for the size of the original pool of such terms.

2. The number of repression-relevant terms that the person fails to remember should be proportionally greater than would be expected relative to that person's more general long-term recognition rate. This correction was achieved by using all other correctly recognized terms from the initial memory task, those having no theoretical relevance to repression, as a general reference group and determining their retention percentage on the second recognition task. This general reference group included words that were correctly recognized initially and that were unfavorable and attributed to others, neutral and attributed to self or others, or favorable and attributed to self or others.

The final repression score was *percent retention from general reference group minus percent retention from repression-relevant group*. Higher scores in a positive direction suggest repressive forgetting of aversive information, whereas scores near zero or negative scores contraindicate repression and might be taken to suggest sensitization to aversive information.

These percentage correction score distributions for males and females were very similar and approximated normal distributions. The latter observation was confirmed by chi-square goodness-of-fit tests (Maxwell, 1961) applied separately to the distribution of male, $\chi^2(2) = 2.93$, $p > .20$, and female, $\chi^2(2) = 2.23$, $p > .30$, repression scores. Neither distribution deviated statistically from a normal curve.

The projection scores were split independently by sex at their median values (two for

males and three for females), thereby defining high and low projectors. Repression scores (see Table 2) were then analyzed by means of a 2×2 factorial (Level of Projection \times Sex) analysis of variance for unequal cell frequencies (Winer, 1962). There were two significant main effects. Female subjects had higher repression scores than males, $F(1, 43) = 10.48$, $p < .005$, and low projectors had higher repression scores than high projectors, $F(1, 43) = 9.56$, $p < .005$. No Sex \times Projection Level interaction was obtained, $F(1, 43) = 1.02$, $p > .30$.

Control Analyses

Two control analyses of the data were conducted to lend further confidence to the methodology on which the results are based. The first of these concerned the effectiveness of the laboratory analogue that was devised to activate defensive styles in the subjects. Can it be demonstrated that the subjects were responding within an evaluative context in which arousal of defensive behavior might be expected? The instructions indicated that the evaluative terms on the tape came from a survey of mothers asked to describe their college-age sons. The same or very similar instructions have proven effective in eliciting an evaluative set in a host of previous laboratory studies (reviewed in Heilbrun, 1973a) as gauged by the establishment of a theoretically coherent network of results. Effectiveness of the procedures could be shown if the defensive style relationships found in this study when the subjects processed terms ac-

Table 2
Repression Scores as a Function of Level of Projection and Sex

Sex of subject	Level of projection						Com- bined <i>M</i>
	High			Low			
	<i>n</i>	<i>M</i>	<i>SD</i>	<i>n</i>	<i>M</i>	<i>SD</i>	
Male	17	-12.13	9.62	13	-4.25	12.04	-8.71
Female	9	-3.70	14.30	8	11.83	12.90	3.61
Combined <i>M</i>		-9.21			1.88		

Note. The higher the scores in the positive direction, the greater the repression. Grand *M* = -4.24.

tually from the tape (and presumably from mothers) could not be replicated for the terms incorrectly "recognized" on the initial memory task and not having a maternal source.

Projection and repression scores were derived for all subjects from the pool of adjectives that had not appeared on the maternal tape but had been checked by each subject as being on the tape. The same statistical analyses were performed as reported earlier in this section. Male ($M = -1.50$) and female ($M = -.47$) projection scores failed to differ, $t(45) = .81$, $p > .40$, as before, and an analysis of variance disclosed no sex difference in the repression scores of males ($M = -15.49$) and females ($M = -23.25$), $F(1, 43) = 1.29$, $p > .25$. Furthermore, no relationship between projection and repression was found, $F(1, 43) = .05$; male high projectors ($M = -14.49$) and low projectors ($M = -16.49$) had virtually identical repression means, and females found to have low and high levels of projection also had very similar means (-26.05 vs. -20.76). Thus, relationships involving defensive styles were obtained only for those terms presented within an evaluative context.

The second control analysis considered the repression score, based on the difference between the retention rate for one group of words comprised totally of unfavorable terms and another group comprised of words that were largely neutral or favorable. It might be contended that the failure to retain the key unfavorable terms for females (or low projectors) is attributable to their more general aversion to all the unfavorable words that appeared in the critical list whether they were considered by the subject to be self-characteristic or not. This failure to recognize negative evaluative terms coming from a maternal source has been demonstrated in a previous experiment using the same words as in the present experiment, similar instructions, and an auditory threshold discrimination procedure (Heilbrun, 1973b). In that study college males showed a specific recognition deficit for negative maternal evaluative terms spoken in a female voice near threshold volume. Examination of the mean number of

adjectives within each qualitative category on the critical list that were correctly recognized on the initial memory task should shed light on this issue. If repression score elevations for females and low projectors are attributable to a more general problem in remembering negative terms having a maternal source, it would be expected that this would also appear in the recognition performance of these two groups immediately following the presentation of the taped list and before the words were sorted into those characterizing the self and others.

Table 3 presents the mean number of recognitions within each qualitative category on the initial memory task for the four Sex \times Projection Level groups. A $2 \times 2 \times 3$ (Level of Projection \times Sex \times Qualitative category) factorial analysis of variance for unequal cell frequencies revealed only one significant effect. Females recognized more critical words ($M = 45.24$) than did males ($M = 40.47$), $F(1, 35) = 5.86$, $p < .025$. However, the absence of a Level of Projection \times Qualitative Category or Sex \times Qualitative Category interaction offered no support for the contention that low projectors or females experienced a more general aversion to unfavorable critical terms.

Discussion

Two basic questions were considered in the present experiment. First, given the option of dealing with unfavorable information about themselves defensively by either projective or repressive styles or nondefensively, will there be a difference in the use of either style between males and females? The results indicated that both sexes used projective attribution of unfavorable characteristics to others to about the same degree. However, females were more prone to use the selective forgetting of unfavorable characteristics involved in repression to a greater extent than males. Since sex differences have received little systematic attention in previous studies of repression, it is difficult to say what the implications of the present results might be for prior research results. They do argue, however, for more careful attention to subject sex in subsequent investigations of repression.

Table 3

Mean Number of Correct Recognitions on the Initial Memory Task for Males and Females Differing in Use of a Projective Defensive Style

Type of subject	Category of evaluative term		
	Favorable	Neutral	Unfavorable
Male			
High projector	13.29	12.47	14.29
Low projector	14.00	12.77	14.23
Female			
High projector	14.11	14.56	15.11
Low projector	16.75	15.00	15.12

The repression results taken alone, even with the sex difference, could have easily taken their place among those of a host of other studies that have sought to demonstrate motivated selective forgetting but, when reviewed as late as 1974, led Holmes (1974) to conclude that "the continued use of repression as an explanation for behavior does not seem justifiable" (p. 651). The overall rate of retention of self-attributed unfavorable terms was only about 4% less than that found for all other combined terms; considering all subjects, this is hardly robust evidence for repression. However, the present investigation went one step beyond its predecessors by offering subjects alternative ways of defending against aversive information. The second question under investigation then became not whether repression (or projection) can be demonstrated but whether, given these alternatives, subjects can be shown to make primary use of one or the other defense. The results suggest that the subjects did tend to use a primary defense style, whether the subject was male or female. Those who projected more usually repressed less, and vice versa. It is worth noting in this context that seven subjects showed no evidence of either a projective or repressive style of defense. This serves as a reminder that many defensive styles are available to cope with threatening information and that the present methodology assessed but two of these. It is also true that the use of either style within this study as a primary defense does not necessarily imply that the same style is the dominant defense in real life. It is the generally inverse rela-

tionship of repression and projection found in this study that is held to be significant to both laboratory investigation and natural behavior.

Holmes (1974) has challenged the interpretation of laboratory studies of repression that have presumably demonstrated the occurrence of this defense mechanism. He considers response competition to be a more parsimonious explanation of the selective loss of threatening material, and two of his own studies (Holmes, 1972; Holmes & Schallow, 1969) encourage this viewpoint. In the earlier of these, the retention of nonevaluative nouns was found to be just as impaired by the introduction of unrelated interpolated material between exposures as by associating word exposure with threats. In the follow-up experiment, a deficit in retention followed not only the association of words with threat but also the association of words with ego-enhancing instructions. It was the cognitive activity associated with either negative or positive evaluation that was thought to be distracting and to interfere with subsequent recall of the words. Holmes' research does demonstrate quite clearly that memory deficits associated with ego threat can be accounted for in response interference terms. Furthermore, his assumption that these deficits are mediated by attentional factors is bolstered by the fact that the impaired recall of terms associated with threat, ego enhancement, or response interference was indistinguishable from control group performance after debriefing and the refocusing of attention on the critical words. Holmes was aware of the inferential problem

of *proving* that the conditions of memory loss for the repression group were the same (or were different) from these for the response interference or ego-enhancing groups, however.

The significance of this inferential problem for the present repression results is two-fold. On the one hand, all subjects were given the same conditions of exposure to the critical words prior to the final recognition task. After initial recognition was measured, each subject judged the relevance of the evaluative terms to self and others and then was maintained on a buffer task for the delay period. Furthermore, repression was assumed only when a specific class of evaluative terms suffered selective loss—those having a maternal source that were unfavorable and assigned as self-characteristic. A response interference interpretation, which assumes the importance of a source of stimulation other than threat, would have to account for why this narrow class of terms suffered more interference than other terms for the same individual. This cannot be reasonably explained in terms of the experimental procedures that were standard for all subjects; it requires an explanation based on the way in which each subject processed the critical terms.

If individual differences in processing negative self-relevant information were invoked as an explanation of selective memory loss, we would be right back to considering repression as a defensive mechanism. It is here that I agree with Holmes in emphasizing response interference and attention. At least as far back as Dollard and Miller's (1950) influential treatise explicating psychoanalytic concepts in learning theory terms, repression has been considered by many as a consequence of anxiety-generated response interference resulting in an attentional shift from threatening material to something more neutral. Given an adequate stimulus, a previous aversive thought is prevented from occurring by the incompatible occurrence of a "stop thinking" response. A similar explanation involving response competition seems to fit the repression results in the present study.

Perhaps one thing that might be accomplished by the present experiment would be to move the investigation of the defense

mechanisms closer to the mainstream of personality research. Rather than concentrating on laboratory demonstration of the defense mechanisms as clinical, trauma-induced phenomena, study of defensive styles could be focused on the ways the normal individual deals with aversive information that threatens self-esteem or emotional well-being. This would broaden our inquiry to a wider range of interesting questions such as the social origins of different defensive styles and the conditions under which defenses are invoked, circumvented, or shifted.

The Right to Treatment: Issues in the Treatment of Homosexuality

Ellie T. Sturgis and Henry E. Adams
University of Georgia

The current controversy regarding the classification and modification of homosexual behavior appears to have been stimulated by pressures on professional organizations exerted by groups such as the Gay Liberation Movement. As a consequence, Davison has argued against the use of sexual reorientation procedures for homosexuality. Davison's recommendation appears motivated by sociopolitical factors rather than psychological evidence, resulting in a neglect of accurate assessment of the needs of the individual. We maintain that the question of the abnormality of homosexuality is an empirical issue, but this issue is irrelevant to the treatment of the individual. The criterion of abnormal behavior is not a necessary prerequisite for behavior modification, since behavior therapists can and do intervene with problems of everyday living to enhance personal effectiveness. The decision concerning the modification of sexual orientation should be based on the life circumstances and values of the individual rather than the value systems of the therapists. We strongly urge clinicians to take a tolerant and impartial view of sexual problems without imposing homosexual, heterosexual, or other value systems on their clients.

Davison (1976), in his discussion of the ethical challenge presented by an examination of homosexual behavior, has raised a number of important and valid issues. However, many of Davison's arguments appear to be based on social and political rhetoric rather than empirical evidence. Such an approach results in a neglect of the assessment of the needs of the individual, which allows therapists to institute, when necessary, an intervention strategy tailored to the requirements of the individual case. If such an assessment is not conducted, the rights of the client may well be violated.

Davison's position that the homosexual be denied the right to modification of sexual orientation violates the right of the individual to treatment and imposes arbitrary values of the clinician in the same manner as the clinician who assumes that all homosexuals should receive treatment for sexual reorientation. The purpose of this discussion is to insure an objective and scientific examination of homosexuality and other target behaviors independent of the current social and political pressures exerted by social activist groups.

What Are Appropriate Target Behaviors?

In his discussion of threats to the ethical foundations of behavior therapy, Davison (1976) challenges the ethics involved in the selection of target behaviors for modification. He cites examples of test anxiety and individuals who lack assertive skills. He questions why therapists treat the "identified client" rather than the systems that produced the anxiety or the individuals who violated the rights of the nonassertive person. A therapist's decision to modify the group behaviors of society rather than behaviors of an individual is legitimate. However, the logical consequence of such a decision implies that the same ethical considerations be applied to society as are applied in the case of an individual. Thus, the intervention must be requested by society, there must exist adequate treatment procedures, and the clinician must know the effectiveness of the treatment program as well as positive and negative side effects.

Particularly relevant to the issue of who should be treated is Davison's (1973) earlier discussion of countercontrol. In that article, he indicated that a therapist cannot force a client (society) to change if that client does not desire to modify a behavior and/or value system. Is society less complex than the individual? The active cooperation

Requests for reprints should be sent to Henry E. Adams, Psychology Clinic, Department of Psychology, University of Georgia, Athens, Georgia 30602.

of the client is required for any treatment method to be effective. Is this not also true for society?

Even though social change is often a desirable goal, it is not particularly evident that behavior therapists have a sufficient data base to initiate or effect such changes. With individual clients, therapy can be objective, empirical, and ethical; however, these values seem to escape us when we discuss society as the client. Unless behavior therapists maintain the same professional values with society that they maintain with individuals, they become political activists rather than psychologists. It is questionable that psychologists interested in social change have any more data for their opinions than do politicians.

Are Therapists Neutral on the Homosexual Issue?

Davison (1976) supports Halleck's (1971) contention that therapists never make ethically neutral decisions. This is a legitimate argument, since research has indicated that the therapists often serve as a modeling and moral agent for the clients (Bandura, 1969). By agreeing to a treatment goal, the clinician conveys the ethical and philosophical approval of the change. The nonneutrality of the therapist is an issue in any treatment procedure. However, Davison implies that the situation is more serious when homosexuality is the issue. Only subjective opinion supports this contention. It is unlikely that therapists are more biased about homosexuality than other problems such as pedophilia, sadism, depression, or schizophrenia. Therefore, to propose that a client not be treated unless the therapist is neutral is to eliminate the helping professions. Value judgments are made about homosexuality as well as for other behavior patterns whether or not society accepts the condition as appropriate. Halleck (1976) contends that although values are always present in a therapeutic situation, the problems are simplified when a comprehensive assessment of the case is conducted. As the circumstances of the behavior pattern vary, it is likely that clinicians will alter their opinions and values accordingly. Halleck argues that a comprehensive assessment increases the likelihood that intervention will not be haphazard. It is further suggested that after the assessment and formulation of any problem behavior regardless of its nature, therapists consult with clients, inform them of their opinions about the problem, discuss possible treatment alternatives, and discuss implications of the alternatives. Included should be a clear statement of the therapist's values that the client can evaluate in accepting or rejecting treatment alternatives. Such an approach decreases the likelihood that a client would unknowingly be influenced by the

value systems of the therapist and also allows the individual to exercise greater personal control over possible consequences of treatment procedures.

Homosexuality: Normality or Abnormality or Is There No Cure Without a Disease?

The issue of abnormality is inevitably raised when psychologists consider the phenomenon of homosexuality. The research data have supported both the "mental health" of the homosexual (Gagnon & Simon, 1973; Green, 1972) and the pathology of the individual (Bieber et al., 1962). Davison, in a telling argument, maintains that before conclusions can be made that etiology factors are pathological, the resultant behavior pattern must first be labeled *abnormal*. Even if a homosexual individual exhibits nonsexual pathological behaviors, it remains to be demonstrated that such behaviors are associated with or are the result of the homosexual condition. Abnormal patterns of behavior observed in homosexuals may be independent of homosexuality and should not be used as a basis for a decision about the abnormality of homosexuality.

The abnormality of homosexual behavior, like the classification of any behavior pattern, is an issue to be resolved empirically rather than through verbal discourse or through the vote of a professional body (Adams, Doster, & Calhoun, 1977). Nevertheless, it does not follow, as Davison suggested, that the abnormality of homosexuality or any other behavior is a necessary or sufficient prerequisite for intervention. Many individuals who seek the aid of a psychologist are normally functioning individuals who experience difficulties in some aspects of their lives. Should the issue of treating individuals who report dissatisfaction with their pattern of sexual preferences be different from treating individuals who are dissatisfied with behavior patterns in nonsexual response systems? When clinicians respond differently to homosexuality than to other problems, are we not reacting to social or political pressures rather than to the basic issue of treatment?

For the clinician, the question of adaptive or maladaptive response patterns should be considered in reference to the individual who requested help. Psychological intervention for maladaptive behavior is warranted when the behavior pattern causes the individual discomfort or distress. However, it does not necessarily follow that behavior therapists should offer assistance only to individuals labeled as abnormal.

Behavioral techniques have often been used with nondeviant behaviors to enhance positive aspects of behavior or increase the personal effectiveness

of an individual. Such target behaviors have included enhancing social skills, assertiveness, study behavior, training in child management procedures, and problem-solving techniques (Goldfried & Davison, 1976). The development of modification techniques does not necessarily indicate that the therapist sees the client as having a "disease" as Davison inferred.

Is Social Prejudice the Primary Agent in Distress?

Davison stated that social prejudice contributes to the problems of the homosexual and causes the individual undue distress. Although this is a valid observation, he implies that social prejudice is unique to homosexuality. On the contrary, social pressures exist for most individuals who deviate from societal norms, regardless of the direction of the deviation. Such individuals are frequently subjected to criticism and discrimination including those who have sought psychological assistance; those of a different race, ethnic, or social group; and even individuals who deviate positively (i.e., high-achieving women or creative individuals; Alper, 1974; Farina & Ring, 1965; Lamy, 1966). The ability of an individual to adapt to such social pressures and to perform adequately is appropriately considered one element of normal functioning. Regardless of the desirability or undesirability of social prejudice, to assume that homosexuals experience more prejudice than others do is questionable. The role of social prejudice in specific deviations (positive or negative) can be more appropriately answered through empirical investigation than through armchair speculation. Until such evidence is available, one cannot conclude that social pressure is the critical factor in the development of distress and desire for change in the homosexual but not in the development of distress and the desire for change in other patterns of behavior.

Davison (1976) stated that society does not attribute problems to heterosexuals on the basis of their sexual behaviors. The validity of this statement is questionable. For example, most rapists are heterosexual, but they are viewed as having problems related to their sexuality. Since the time of Freud, psychological literature has been filled with cases in which the problems or abnormal behavior patterns of heterosexuals have been attributed to fixations at stages of psychosexual development or have resulted from unresolved sexual conflicts. The validity of such hypotheses is irrelevant. However, the impact of Freudian thought on society can neither be estimated nor denied.

Even if society is the causal agent of distress in homosexuality, it does not follow that the solution

is to modify the attitudes of society, as was indicated in our previous discussion of this issue. Although psychologists should try to educate the public concerning the factual issues related to homosexuality (or other behavior patterns), psychologists should refrain from presenting information that lacks a data base. Social propaganda or reeducation efforts that are based on personal opinions rather than empirical evidence can have drastic consequences for society and for the profession. Excellent examples of the danger of such campaigns are the disease concepts of "mental illness" and popularized myths of alcoholism (Rosenhan, 1973; Sobell, Sobell, & Christelman, 1972).

Do Effective Modification Programs Reinforce Societal Beliefs?

Begelman (1975) and Davison (1976) maintain that the very existence of reorientation programs for homosexuality constitutes a significant causal element in reinforcing the doctrine that homosexuality is undesirable. However, the authors fail to substantiate the claim with objective data. A review of recent popular publications concerning behavioral techniques such as Orwell's (1949) 1984 and Burgess' (1962) *A Clockwork Orange* indicates that the public is well aware of the possible dangers of behavioral control, but they are less aware of possible benefits of behavior modification techniques.

A review of the work on "brainwashing" following the Korean War (Brownfield, 1965) indicates that very effective programs were developed that elicited large behavior changes in individuals exposed to these procedures. However, the mere fact that the programs effectively changed attitudes, beliefs, and behaviors of the captives did not cause the public to view the captives as "abnormal." To the contrary, the public outcry was directed at the techniques and the individuals who developed them. More recently, similar public alarm has occurred regarding behavior modification programs in the prisons, schools, and other institutions. Davison has responded to these public criticisms by issuing statements defending behavior therapy to a number of senators, the American Civil Liberties Union, U.S. Department of Health, Education, and Welfare, as well as to a number of magazines and newspapers (Davison, 1974; Davison & Stuart, 1975). If a society considers the target behavior of effective treatment procedures as undesirable, why does society object to the implementation of treatment programs that may be effective with behaviors clearly considered deviant, such as crime? Contrary to Davison's

position, the evidence suggests that society objects to any procedure potentially capable of controlling behavior, regardless of the nature of the behavior. Further, it is doubtful that the availability of techniques encourages their use. The rigorous opposition to behavior modification techniques well illustrates this point.

Are Sexual Preferences Equivalent to Sexual Values?

Davison (1976) seems to assume that sexual preferences of individuals determine their values concerning sexual behavior. The literature on sexual behavior would suggest that this is not always the case. There are numerous examples in which individuals report experiencing annoyance and/or shame concerning patterns of sexual gratification but are unable to bring the patterns under self-control. Such case and group studies involve such sexual patterns as impotence, frigidity, homosexuality, fetishism, transvestism, pedophilia, and sadism (Davison, 1968; Kohlenberg, 1974; LoPiccolo, Stewart, & Watkins, 1972). The problem of incongruent values and preferences is best illustrated by many secondary homosexuals who are married and/or engage in heterosexual encounters but have homosexual arousal. Davison's argument that the homosexual seeks treatment primarily because of social pressures appears to neglect the possibility that there are clients who may actually wish to alter their preference to be congruent with their values rather than changing their value system. The decision to change preferences and/or values should not be made *a priori* but should be determined by aspects of each case.

A Proposal for Therapy with Homosexuals

Davison (1976) and Silverstein (Note 1) have proposed that all individuals with homosexual preferences be treated by desensitizing them to their guilt about homosexual preferences and lifestyles. Such a standardized procedure appears to be a return to a state of affairs in which it was not possible to tailor treatment procedures to the particular needs of the individual's case. Indeed, one distinctive characteristic of behavior modification is that these procedures are appropriate for altering a variety of behaviors. Any *a priori* decision to use only specific techniques eliminates one advantage of behavior therapy that allows the clinician to select treatment procedures appropriate to the individual case. Bieber (1973) has distinguished psychoanalysis and behavior therapy on this very basis.

Critical to the selection of any treatment plan

is a careful assessment of the client's current functioning. The clinician should delineate problem behavior(s) along with possible antecedent (or stimulus) events and the consequent or maintaining factors. A behavioral formulation views homosexual preference as a learned pattern of behaviors that is acquired by individuals through their experiences and that may be maintained or modified in the same way that other behaviors are maintained or modified. Possible targeted behaviors for intervention can include such difficulties as negative attitudes toward the object of sexual preference itself, a desire for sexual reorientation, dissatisfaction with the "gay" lifestyle, interpersonal difficulties in homosexual and/or heterosexual social exchanges, guilt or negative reactions toward the self, sexual dysfunctions with homosexual and/or heterosexual partners, negative attitudes toward members of the opposite sex, or any other personal difficulty that an individual (heterosexual or homosexual) can exhibit. The nature of a problem behavior is not determined when the client states that he or she is homosexual or even that he or she is dissatisfied with the status of being homosexual. Only when a target behavior is thoroughly defined and the antecedents and consequences are determined can the therapist conceptualize the problems and suggest various treatment procedures to the client.

In Davison's (1976) discussion of the termination of preference change programs, he admits that such a move runs the risk of denying treatment to homosexuals who desire an orientation change, not on the basis of social pressures but based on "a sincere desire for things that in our culture are usually part of the heterosexual package—a spouse and children" (Davison, 1976, p. 161). As one solution, he proposes that clinicians accept such risks. This position appears to violate an earlier position adopted by Davison in defense of behavioral treatment for institutionalized individuals. In that article, he stated that "we cannot deny mental patients their right for treatment" (Cashman, 1974, p. 5). How does one justify treatment for institutionalized individuals whose consent, according to Davison, may sometimes be coerced and then refuse to offer treatment for the purpose of sexual reorientation to a homosexual because the decision for treatment may have resulted from social pressure? The decision for treatment should be made by the client rather than the therapist and should be based on an understanding of all relevant aspects of the situation and the client's desires.

In summary, the position taken by Davison appears to be based on philosophical beliefs that

ignore empirical data. His position violates the right of the individual to select treatment goals. The purpose of this article was not to espouse particular views concerning the nature and treatment of homosexuality. To the contrary, the intent was to challenge Davison's position in order to stimulate relevant research and insure protection of the client's right to treatment. Through careful consideration of issues related to the modification of homosexuality, it is hoped that clinicians will arrive at their own conclusions based on rational, objective logic resulting from an evaluation of empirical evidence and the needs of the individual case. As clinical scientists, we can ill afford to make our decisions on the basis of social pressures or personal values. The state of a science cannot be decided by popular vote or verbal mandate. To be effective psychologists, we must ultimately let the data and the requirements of individual cases guide us in the formulation of our views and treatment procedures.

Not Can but Ought: The Treatment of Homosexuality

Gerald C. Davison

State University of New York at Stony Brook

My earlier proposal to terminate change-of-orientation programs rests on moral not empirical grounds. Arguments based on whether therapists can or cannot alter sexual preferences are irrelevant. Therapists, moreover, have no abstract responsibility to accede to requests from clients for certain types of treatment; we work within a host of personal, conceptual, and even legal constraints. Therapists are characterized better as secular priests than as professionals applying ethically neutral techniques. Therapists should attend to large-scale social and political factors in their clients' lives as conscientiously as they attend to intrapsychic and interpersonal variables; our students should study philosophy and politics as well as learning theory and research design. Finally, to urge that therapists desist from sex reorientation programs is not tantamount to exhorting them not to see homosexuals in therapy; indeed, renouncing these widely used programs can help professionals focus on the problems homosexuals (and others) have, rather than on the so-called problem of homosexuality.

I am grateful for the invitation to respond to Sturgis and Adams' (1978) critique of my proposals to terminate change-of-orientation programs for homosexuals (Davison, 1976).

Given the cultural biases against homosexuality, it is problematic to assert that people who ask for change of orientation are expressing a "free wish." We have been remiss in examining why people request certain kinds of treatment (cf. Silverstein, Note 1).

Some of the misunderstanding of my position may stem from a confusion in levels of discourse. Even though I am prepared to argue that *individuals* can benefit from a renunciation of change-of-orientation programs, my proposals are more properly viewed as *institutional* in nature (Rapaport, 1977), that is, as concerned with societal-ethical constraints on human behavior within a framework that is more broad than that familiar to most psychotherapists. Certain issues are better discussed at one level than at another. I believe the issue of therapy for homosexuality should be addressed at an institutional level.

Let me turn now to some of the specific points raised in the critique of Sturgis and Adams

(1978). They are entirely correct to claim that my arguments are based on sociopolitical factors rather than on empirical considerations. They have properly grasped the thrust of my 1976 article, but I do not share their displeasure at my being moved by ethical rather than empirical concerns. What they fail to understand is that the issues we are dealing with as therapists are, indeed, philosophical-ethical ones, and these moral considerations transcend research considerations. To discourse on the empirical level, as they do very well, is simply to misperceive the essence of the issue. Their critique is irrelevant to my article.

Those who continue to offer change-of-orientation treatment to homosexuals do not have a monopoly on sensitivity to clients' rights. I do not believe that the issue can be settled by arguing, as they do, that a therapist has some sort of abstract responsibility to satisfy a client's expressed needs. It is not that simple. As Begelman (1975) has pointed out, therapists constrain themselves in many ways when clients ask for certain kinds of help. There is a host of client requests that therapists do not honor. In fact, the courts (cf. *Kaimowitz v. Michigan Department of Mental Health*, 1973) are becoming involved in denying the "voluntary" requests of patients for certain types of treatment. Requests alone have never been a sufficient criterion for providing therapy.

Clients, moreover, make certain requests of

I wish to thank David A. Begelman for his comments on an earlier draft of this paper.

some therapists and will not do so with others—though, admittedly, it is difficult to collect good data on this. Therapists are purveyors of social ethics, and it is better to own up to this secular priest role (cf. London, 1964) than to continue pretending that it does not exist.

Sturgis and Adams (1978) are correct in asserting that the normality or abnormality of a behavior is irrelevant to whether therapists should try to change it. My earlier discussion of the normality status of homosexuality could have been omitted, but at the time it seemed worthwhile to review both the evidence and the logic behind the futile attempts that have been made to address the issue.

My colleagues do not show an understanding of the social nature of "empirical evidence." Psychologists, like other scientists, do not merely go out and "gather data." They hold preconceived ideas of what they will find and how they will decide they have found it (Davison & Neale, 1978). Scientists adopt paradigmatic ways of defining the problems they will study and how they will study them (Kuhn, 1962). We do not, as Sturgis and Adams (1978) suppose, simply "arrive at . . . conclusions based on rational, objective logic resulting from an evaluation of empirical evidence" (p. 169).

As noted above, their assertion that I based my arguments on social and political considerations is accurate, but to say that *therefore* I am neglecting a careful assessment of the needs of the individual does not follow, certainly not logically or even empirically. The "psychological needs" of a person are seen by Sturgis and Adams as necessarily separate from their social-political needs or pressures. This separation is neither valid nor necessary, and my exhortation is that mental health professionals expand their perspectives to include those sets of variables that are too often overlooked. It is certainly not inherent to a social-learning approach to ignore political and ethical variables; in fact, our general orientation is well suited to this more comprehensive assessment enterprise, as others have creatively demonstrated (e.g., Bandura, 1969; London, 1969; Ullmann & Krasner, 1975).

Sturgis and Adams (1978) contend that "to propose that a client not be treated unless the therapist is neutral is to eliminate the helping professions" (p. 166). This is erroneous on two grounds. First, I am not proposing that clients not be treated unless therapists are neutral. Rather, I am suggesting (after Halleck, 1971) that therapists *cannot* be neutral and that they should realize this. Nowhere, either in what I

have written, taught, or practiced, do I advocate we not do therapy because we are not neutral. Second, to admit to one's biases hardly eliminates the helping professions. If anything, it poses exciting challenges, not the least of which concerns the content of clinical training. Courses in politics, sociology, and philosophy would seem at least as appropriate as courses in learning and statistics.

Having cited Halleck (1971) extensively in my 1976 article, it is not surprising that I generally agree with his comments on that effort (Halleck, 1976). A comprehensive assessment is impossible to argue with, and for therapists to make clear their biases (value systems) is precisely what I am proposing. Along with Sturgis and Adams, I agree with this position. But I would ask only that therapists tell a homosexual that his or her sexual orientation is wrong whenever they embark on a change-of-orientation procedure. The alternative, as stated in my 1976 article, is for therapists to be as vigorous in devising sexual enhancement procedures regardless of orientation as they have been in helping homosexuals become less homosexual.

I have been misunderstood (not necessarily by Sturgis and Adams) to have said or implied that I advocate not treating homosexuals. This is hardly the case. It is one thing to say that one should not treat homosexuality; it is quite another to suggest that one should not treat homosexuals. Indeed, I have urged that therapists *do* finally consider the problems in living that homosexuals really have. Such problems are perhaps especially severe, given the prejudice against their sexual orientation. It would be nice if an alcoholic homosexual, for example, could be helped to reduce his/her drinking without having his/her sexual orientation questioned. It would be nice if a homosexual fearful of interpersonal relationships, or incompetent in them, could be helped without the therapist assuming that homosexuality lies at the root of the problem. It would be nice if a nonorgasmic or impotent homosexual could be helped as a heterosexual would be rather than guiding his/her wishes to change-of-orientation regimens. Implicit in my original argument is the hope that therapists will concentrate their efforts on such *human* problems rather than focusing on the most obvious "maladjustment"—loving members of one's own sex.

Perhaps some people can be hurt by my proposals. To suggest otherwise would be naive. But to assume that people are not being hurt by the

prevalent prejudices is at least as naive.¹ I suppose one has to be reminded of the fact that we live in an imperfect world. I trust there are few therapists who deliberately harm their clients. But it is inherent to my comment that great numbers of people are being hurt by the availability of change-of-orientation programs, and these include individuals who themselves are not seeing therapists. I believe far fewer people would be distressed if we eliminated that option and instead devoted our energies to (a) societal prejudices and (b) to the whole range of problems that homosexuals, heterosexuals, and those in between, have as we all negotiate our way.

I hope the debate continues.

¹ Begelman (1975) takes a different approach in countering the argument that these proposals against sex orientation change are misguided because they may not make people happy. He questions whether the right thing for therapists to do is necessarily what will make their clients happy. Sometimes it is ethical to make a client *more* distressed rather than less so, as when the client's behavior is morally wrong, or when, as is the issue here, the goals of the treatment are ethically questionable.

Brief Reports

Modality, Self-disclosure, and Gender as Determinants of Psychotherapeutic Attraction

Michael R. Kowitt and John P. Garske
Ohio University

The present study investigated the effects of therapy modality and the self-disclosure tendency and gender of the subjects on therapeutic attraction. Forty high and 40 low scorers on a modified self-disclosure questionnaire were asked to rate audiotapes of simulated therapy sessions on several dimensions. The primary results were as follows: High self-disclosers preferred client-centered therapy, whereas low self-disclosers preferred systematic desensitization; client-centered therapy was perceived as providing a greater opportunity for self-exploration, whereas systematic desensitization was perceived as more effective; low-self-disclosing males and high-self-disclosing females rated the therapist as attractive but ineffective; and females were more attracted to systematic desensitization, whereas males were more attracted to client-centered therapy.

Clinical researchers have contended that a subject's attraction to a specific therapeutic modality has a significant impact on the process (Goldstein, 1971) and outcome (Devine & Fernald, 1973) of psychotherapy. The present study investigated this interactive effect in a controlled analogue design. The major hypothesis was that high-self-disclosing subjects would be more attracted to client-centered therapy, whereas low-self-disclosing subjects would be more attracted to systematic desensitization.

College undergraduates (94 males, 84 females) completed Panyard's modified version of the Journal Self-Disclosure Questionnaire and listened to one of two simulated audiotapes of excerpts of psychotherapy sessions. One tape depicted client-centered therapy; the other depicted systematic desensitization. The actors were the same in each (female client, male therapist). Each tape contained segments of the 2nd, 3rd, 8th, and 10th therapy sessions; Sessions 2 and 10 were identical for each to control for the client's report of her problem (interpersonal difficulties) and her evaluation of the effectiveness of the therapy (moderately improved), respectively. The tapes were also matched for duration (10 minutes). Following the tape presentation, each subject rated seven items derived from Goldstein's (1971) Tape Rating

Scale to evaluate the therapist, the technique, and the therapy's effectiveness.

A $2 \times 2 \times 2$ factorial analysis of variance was performed on each of the seven rating variables. The factors were therapy type (client centered/systematic desensitization), subject self-disclosure (upper/lower quartile), and subject sex. Post hoc analyses of the interactions were performed using Cicchetti's procedure. The major finding involved the hypothesized interaction between therapy type and subject self-disclosure ($p < .02$); the low-self-disclosure subjects preferred the therapist who used systematic desensitization ($p < .05$), whereas the high-self-disclosure subjects tended to prefer the client-centered therapist. Low self-disclosers also rated the client-centered therapist as providing less help ($p < .05$). Other significant findings were: Client centered therapy was perceived as providing a greater opportunity for self-exploration, whereas systematic desensitization was perceived as more effective (despite the matched effectiveness of the tapes); low-self-disclosing males and high-self-disclosing females rated both therapists as more attractive but less ineffective; females generally preferred systematic desensitization, whereas males preferred client-centered therapy.

The results revealed that both subject and modality variables independently and interactively affected subject evaluation of psychotherapy. Ostensibly, high self-disclosers were attracted to a modality (client-centered therapy) that matched

their preference to reveal themselves, whereas low-self-disclosers preferred a modality (systematic desensitization) with structure and direction. There were also complex subject-gender effects. Although these data might be suggestive of differences in actual therapy outcomes (Devine & Fernald, 1973), they should be viewed as preliminary, pending extensions to clinical populations. Moreover, the design was restricted by its use of extreme groups of self-disclosers and a single client-therapist gender pairing.

Factor Analysis of the Ward Atmosphere Scale

Lynn Alden

University of British Columbia, Vancouver, Canada

Eighty-seven inpatient volunteers completed the Ward Atmosphere Scales (WAS) and semantic-differential ratings of their ward. Results of a components analysis did not support Moos's rational grouping of WAS items into 10 dimensions, but they suggest that a global evaluation dimension might underlie 8 of the 10 subscales.

Clinicians are increasingly using measures of the treatment environment in an attempt to identify characteristics of psychiatric treatment programs related to treatment efficiency and effectiveness (Ellsworth & Maroney, 1972; Moos & Schwartz, 1972; Sidman & Moos, 1971). Among the more widely used instruments are a series of measures developed by Moos and his colleagues, including the Ward Atmosphere Scale (WAS; Moos & Houts, 1968) and the Social Climate Survey (Moos, 1968). Because these instruments are gaining widespread acceptance in clinical settings (Milby, Pendergrass & Clarke, 1975; Otto & Moos, 1974), it is important to understand the nature of the information conveyed by the WAS. One question that arises is the extent to which each of the 10 WAS subscales conveys unique information about the environmental unit. Although Moos has not found sufficiently large subscale correlations to warrant collapsing subscales, a recent analysis by Wilkinson (1973) suggested that a single global dimension might underlie environmental measures of this type. Further, the pattern of WAS subscale correlations with the Perception of Ward scales (Ellsworth & Maroney, 1972) and with such factors as patient satisfaction (Houts & Moos, 1969) suggests that a cluster of the WAS subscales may function as a single unit. This study investigated the number and nature of dimensions tapped by the WAS.

This article is based in part on a dissertation submitted in partial fulfillment of the requirements of the PhD at the University of Illinois (Champaign) under the chairmanship of Donald R. Peterson. The author wishes to thank the members of her committee: Donald R. Peterson, Edward Seidman, Stephen Golding, Julian Rappaport, and Ralph Hakstian.

Requests for reprints should be sent to Lynn Alden, Department of Psychology, University of British Columbia, Vancouver, British Columbia Canada V6T 1W5.

Method

Subjects

Subjects were 87 inpatient volunteers at a psychiatric institution for the criminally insane. Subjects ranged in age from 18 to 65, were unmarried (80%), were likely to have a history of previous psychiatric treatment (59%), and were often judged to be violent (71%). The average subject had an eighth-grade education and had been hospitalized for 2-3 years. The most common diagnosis was character disorder (71%), with 8% diagnosed as neurotic and 21% diagnosed as psychotic. Subjects were distributed over eight small wards. Three wards were described as utilizing a conventional milieu approach; three wards followed a behavior modification format; and two wards were described as existential therapy units.

Procedure

All subjects completed the WAS and semantic-differential ratings of their ward. Six adjective pairs were included as part of the semantic-differential technique, with two scales marking each of the three affective components of meaning. The adjective ratings were made on 7-point scales.

Results

The 10 WAS subscales were intercorrelated, subjected to a principal-components analysis with unities in the diagonals and rotated to a varimax criterion of simple structure. Three factors having eigenvalues greater than 1 emerged. All but two subscales (Anger, Staff Control) displayed high positive loadings on the first factor, which accounted for 50% of the total variance. The second factor, accounting for 14% of total variance, was marked by a high positive loading on the Anger scale. The third factor, accounting for 10% of the variance, was marked by Staff Control.

The semantic-differential ratings were subjected to a principal-components analysis following the procedure described above. Two components emerged: evaluation-activity, which accounted for 40% of the total variance, and potency, which accounted for 29% of the total variance.

Factor scores on the WAS and the semantic differential were computed for each subject following the Alberta general factor analysis program (Hakstian & Bay, 1973). Pearson correlation coefficients were computed between the WAS factor scores and the semantic-differential factor scores. Evaluation-activity displayed a moderate relationship, $r(87) = .48$, $p < .01$, with the first component of the WAS, suggesting that the first component reflected subject evaluation of the unit. Low but statistically significant relationships were found between evaluation-activity and the third component, Staff Control, $r(87) = .21$, $p < .05$, and between potency and the second component, Anger, $r(87) = .22$, $p < .05$.

Discussion

The results of the components analysis do not support Moos's rational grouping of WAS items into 10 dimensions. In general, one global dimension was found to underlie subjects' ratings on eight subscales (Involvement, Support, Spontaneity, Autonomy, Practical Orientation, Personal Problem Orientation, Order, and Clarity). The other two components appeared to be specific components, marked by only one scale each. The correlation between the first component of the WAS and the semantic-differential ratings suggests that this component reflects subject evaluation of the unit. It is worth noting that this interpretation supports the conclusions drawn by Wilkinson (1973).

It may be that the WAS functions largely as an attitudinal measure, tapping how positively a

subject feels about the ward. It might prove worthwhile to investigate the extent to which simple client satisfaction measures can achieve the same ends as more extensive measures such as the WAS.

Defensive Externality and Level of Aspiration

Dorothy J. Hochreich
University of Connecticut

This study tested the hypothesis that increasing the salience of achievement cues will result in higher levels of achievement-striving behavior for one subgroup of externals, congruent externals; defensive externals and those with an internal locus of control orientation will behave in a striving manner regardless of level of cue explication. Ninety-six male subjects, defensive externals, congruent externals, and internals, participated in a level of aspiration task under either "game" or "test" instructions. As predicted, congruent externals showed significantly more realistic striving behavior in the test condition ($p < .006$); internals and defensive externals showed similar high levels of realistic striving under both conditions.

Recent research dealing with the relationship between expectancies for internal-external control and achievement behavior (Hochreich, 1975) suggests the utility of using Rotter's interpersonal trust measure to select two groups of externals: defensive (low-trust) externals, who appear to be ambitious, achievement-oriented persons whose endorsement of external statements primarily reflects a verbal defense against failure; and congruent (high-trust) externals, who seem to be less ambitious and less inclined to react to failure by means of blame projection. Previous studies indicate that depending on the particular circumstances, defensive externals will sometimes behave like internals, sometimes like extreme externals.

Lefcourt (1967) suggested that externals, as compared with internals, fail to perceive the availability of achievement rewards unless achievement cues are made quite explicit. Using three levels of cue explication in instructions for a level of aspiration task, he found that externals showed a marked increase in realistic achievement-striving behavior as a result of greater cue explication, but internals did not vary across conditions. If, however, defensive externals are as achievement oriented as internals, they should react in an internal, striving manner whether or not achievement cues are made salient. The less ambitious congruent externals, on the other hand, may require stronger achievement instructions in order to perform successfully.

Three groups of male subjects (32 per group) participated: defensive externals (external and low in trust, determined by median splits); congruent externals (external and high in trust); and internals (with trust scores representing the full range). Within each group, subjects were randomly assigned to participate in Rotter's level of aspiration board task under one of two instructional sets: game condition (task described as a children's game) or test condition (described as a test of motor skills and ability to assess one's own performance). Results were analyzed using Rotter's nine patterns of level of aspiration behavior. Patterns 1-4 represent relatively realistic, responsive, and achievement-striving behaviors. Patterns 5-9 represent less realistic behaviors (overestimation, underestimation, rigidity, or unresponsiveness to feedback).

Overall, subjects showed more realistic patterns in the test condition than in the game condition, $\chi^2(1) = 3.50$, $p < .10$, two-tailed. The three groups did not differ from each other within the test condition (81.5% of defensive externals, 100% of congruent externals, and 87.5% of internals had realistic patterns). A significant difference was found within the game condition, however (88% of defensive externals, 56.5% of congruent externals, and 81% of internals had realistic patterns), $\chi^2(2) = 4.66$, $p < .10$, two-tailed. As predicted, neither internals nor defensive externals varied across conditions (Fisher's exact probability test, $p = .66$ in both cases), whereas congruent externals in the test condition had a significantly higher

Requests for reprints should be sent to Dorothy J. Hochreich, Department of Psychology, University of Connecticut, Storrs, Connecticut 06268.

proportion of realistic patterns than their counterparts in the game condition ($p = .006$, two-tailed). It appears that high levels of cue explication resulted in improved performance for one subgroup of externals, congruent externals. Defensive externals, like internals, attended and reacted to the availability of achievement reinforcements even when cues spelling out such rewards were not present.

Predictors of Child Noncompliant Behavior in the Home

Rex Forehand, Karen C. Wells, and Ellie T. Sturgis
University of Georgia

The present study examined which data (parent behavior, child behavior, or parent reports) obtained in a clinic setting are the best indicators of child noncompliance in the home. Subjects were 18 mothers and their clinic-referred children. A stepwise multiple regression analysis indicated that two maternal behaviors, beta commands and total rewards, displayed in the clinic were the best predictors of child compliance in the home. The traditionally accepted parent report measures and child behavior in the clinic were not significant predictors of compliance in the home.

Although parent reports and observations of parent-child interactions in a clinic setting traditionally have been used to assess deviant child behavior occurring in the home, many researchers now are using naturalistic home observations. Unfortunately, many clinicians do not perform such assessments due to the time and expense involved. This study examined which assessment procedures in the clinic are the best indicators of child noncompliance, a frequent behavior problem in the home.

Subjects were 18 mother-child pairs. The children, ages 2-9 ($M = 5.1$ years), had been referred for treatment of noncompliance.

Clinic assessment procedures consisted of parent completion of the three scales of the Parent Attitude Test (Cowen, Huser, Beach, & Rappaport, 1970), which pertain to child home behavior problems, and three 20-minute parent-child observations performed over 2 weeks in a playroom. Each observation consisted of 10 minutes in which the mother and child engaged in play activity chosen by the child (free play situation) and 10 minutes in which the mother determined the play activity (command situation). In both situations total (command) rewards, questions, and commands as well as maternal rewards contingent on compliance, as maternal beta commands (vague or interrupted commands to which the child could not comply), and child compliance were recorded. Five 40-minute home observations, performed over 2 weeks, occurred for each mother-child pair. The mother

was instructed to adhere to her daily routine. Child compliance was recorded in the home. Overall reliability, obtained in 20% and 30% of the home and clinic observations, respectively, was 74%.

The 15 independent variables (three questionnaire scales and six behaviors in free play and command situations) and the criterion variable (compliance in the home) were submitted to a stepwise multiple regression analysis. Two maternal behaviors, beta commands in the command situation and total rewards in the free play situation, were significant predictors of child compliance in the home, overall $F(2, 15) = 9.28, p < .01$. The resulting multiple regression equation was $Y = .25166 - .06299 (\text{commands}) + .18623 (\text{rewards})$, indicating a negative relationship between beta commands and compliance and a positive relationship between rewards and compliance. A multiple correlation of .74 indicated that the two independent variables accounted for 55% of the total variance (R^2) in home compliance. A correction for shrinkage, applied to the data to control for the small sample size, reduced the value of R^2 to .51 ($p < .01$). Commands and rewards were responsible for 74% and 26%, respectively, of the predictive ability. The best predictors of child compliance in the home were two clinic-observed maternal behaviors rather than the traditionally accepted parent report measures (questionnaires) or the child behavior (compliance) in the clinic setting.

MMPI Correlates of Drug Addiction Based on Drug of Choice

Lee Trevithick and Harmon M. Hosch
University of Texas at El Paso

Previous Minnesota Multiphasic Personality Inventory (MMPI) research has focused on addict differences based on substance abused. These investigations have largely failed to detect differences using standard univariate methods. The current study used multivariate analysis to detect differences among groups based on drug of choice (amphetamines, barbiturates, or heroin). Sixty-five addicts (48 males and 17 females) served as subjects. Their composite MMPI profile revealed elements of distress, confusion, and depression as well as sociopathy. Multiple discriminant analysis successfully generated two orthogonal functions that accounted for virtually all of the variance between groups. The loadings of each function were analyzed in terms of the behavioral components characterizing each group. The implications for differential treatment strategies and for theories of personality etiology among drug abusers are discussed.

Previous research (Henriques, Arsenian, Cutter, & Samaraweera, 1972) has failed to detect Minnesota Multiphasic Personality Inventory (MMPI) differences among groups of heroin, barbiturate, and amphetamine abusers. This research, however, relied on a univariate analysis of variance that detects group differences only with respect to each individual scale. Since the MMPI scales are interrelated, the present study used a multiple discriminant analysis (Dixon, 1973) to extract scale combinations that might discriminate among the groups.

Subjects were 65 patients involuntarily committed to a residential drug abuse program. The sample included 48 males and 17 females; mean age was 26.75 years, and the mean years of formal education was 11.6. Although virtually all had a history of multiple drug abuse, each had one preferred drug and would use it first when it was available. Groups thus formed included 29 heroin, 13 barbiturate, and 23 amphetamine abusers.

The composite profile showed elevations ($T > 70$) on the Pd , Sc , D , and Pt scales. This confirms the current view of the addict personality as containing elements of distress, confusion, and depression in addition to sociopathy.

The analysis of MMPI profiles by addict group yielded two discriminant functions that accounted for virtually all of the between-group variance and resulted in 46 cases (70%) being correctly classified into their addict group. It

appears then that the weighted combinations of MMPI scale scores can successfully differentiate the three groups of drug abusers.

Scaled vector weights for the first discriminant function were largely defined by the Hs and Pa scales (characterizing the heroin group) at one pole and by the Hy and Sc scales (barbiturate and amphetamine groups) at the other pole. Tentative labels for the poles of this discriminant function might be egocentric anxiety and acute alienation, respectively.

Thus, although the overall profile distinguishes addicts from nonaddicts, combinations of scales discriminate among the subgroups.

These variations imply that differential treatment strategies might be profitably explored. Intervention might be quite different toward an addict who attempts to distract the therapist from his underlying problems (amphetamine abuser), as compared with the approach toward the nonconformist addict who angrily refuses to cooperate (barbiturate abuser). An intriguing question is whether these profile differences reflect the effects of the drug abused or whether preexisting personality differences resulted in the varying modes of substance abuse. Only longitudinal research can provide the answer to this perplexing dilemma.

Predicting Confabulation from the Graham-Kendall Memory-For-Designs Test

Dan Joslyn

Knoxville, Iowa

John L. Grundvig

Veterans Administration Hospital
Tampa, Florida, and the University of
South Florida College of Medicine

C. J. Chamberlain

Veterans Administration Hospital
Knoxville, Iowa

The Embellishment score on the Memory-For-Designs Test (MFD) may be a useful predictor of confabulation in hospital settings. Embellishments are additional features (lines and curves) that alter the original design. Sixteen long-term hospitalized male psychiatric patients who were judged by staff to be habitual confabulators embellished their drawings on the MFD twice as frequently ($p < .01$) as a group of 16 patients of similar age (40-80) and diagnosis who were judged to be nonconfabulators. This was true for both brain-damaged and chronic schizophrenic patients.

The Memory-For-Designs Test (MFD; Graham & Kendall, 1960) is a frequently used device for the gross screening of brain damage. If performance on a series of standard figures falls below certain normative standards, impairment of cerebral function is inferred. As a consequence of studies involving alternative scoring systems for the MFD (Grundvig, Ajax, & Needham, 1973; Grundvig, Needham, & Ajax, 1970), the clinical impression developed that the embellishment score (Taylor, 1961) was related to confabulatory behavior in patients. The purpose of this study was to determine whether these two characteristics occurred in the same individuals. If such were the case, the Embellishment score on the MFD might be used as a predictor of verbal confabulation in the social world of the patient. The term *confabulation* has been used in a variety of ways ranging from the habit of talking without regard for the truth to outright fabrication, with or without insight. Our definition simply required that

the patient habitually tell improbable stories. No specific attempt was made to rule out intentional deception, exaggeration, or delusion.

Subjects were selected from among chronic-care patient populations in the Nursing Home Care Unit and a psychiatric unit for brain-damaged and chronic schizophrenic patients at the Veterans Administration Hospital, Knoxville, Iowa. Treatment teams on the units were asked to identify patients who habitually told stories of doubtful validity, since patients and staff have had long-standing stable interactions. Sixteen patients about whom there was general staff agreement were selected for the confabulator group (M age = 58.9 years, SD = 9.9), and 16 patients, matched for age, were selected for the nonconfabulator group (M age = 60.7 years, SD = 10.5). Nonconfabulators were not chosen to be representative of nonconfabulators in the general population but of nonconfabulating patients in chronic neuropsychiatric wards. Although not matched for diagnosis, the diagnostic representations in the two groups were comparable in terms of the broad categories of chronic brain syndrome and schizophrenia. Major classifications were as follows: confabulators—10 chronic brain syndrome, 5 schizophrenics, and 1 manic-depressive; nonconfabulators—11 chronic brain syndrome and 5 schizophrenics.

The MFD and Wechsler Memory Scale (Form I) (Wechsler & Stone, 1945) were administered to all patients. The authors who administered and scored the MFD and Wechsler Memory Scale were unaware of patient classification on confabulation, thus ruling out the possibility of subjective

bias. The Wechsler Memory Scale was administered to determine comparability of the two groups in memory functioning. The MFD was scored by the conventional Graham and Kendall (1960) scoring system as well as the modified version (Grundvig et al., 1970) of the Taylor (1961) system. The only score from the modified system that is reported in the present study was the Embellishment score. Each of the 15 designs was inspected for the presence of embellishments, that is, *additional* features that alter the original figure. Only 1 point was scored for each design containing embellishment(s). Therefore, the total possible Embellishment score was 15. To determine the reliability of this score, two of the authors and a graduate student assistant scored the MFD for embellishments. Pairwise reliability coefficients among the three scorers were .85, .54, and .47. The lower two coefficients were obtained from an author whose only exposure to scoring was to study Taylor's (1961) thesis, which gave verbal instructions for scoring embellishments. The first coefficient was obtained between the second author and a graduate assistant whom he had trained personally. Some explicit shaping of criterion classification beyond the reading of Taylor's original definitions and examples seems necessary to improve interscorer reliability. Beyond the computation of reliability coefficients, only the Embellishment scores of the second author were used.

Results show that the confabulators embellished their drawings on the MFD almost twice as frequently ($M = 4.9$, $SD = 3.2$) as the nonconfabulators ($M = 2.5$, $SD = 1.5$), $t(30) = 2.79$, $p < .01$, two-tailed. Furthermore, this relationship was true for both brain-damaged and schizophrenic veterans. The mean Embellishment score for the 10 brain-damaged confabulators ($M = 4.9$) was significantly greater than for the 11 brain-damaged nonconfabulators ($M = 2.4$), $t(19) = 1.99$, $p < .05$, one-tailed. Likewise, the Embellishment score for the 5 schizophrenic confabulators ($M = 5.6$) was significantly greater than that for the 5 schizophrenic nonconfabulators ($M = 2.6$, $t(8) = 2.83$, $p < .02$, one-tailed. In addition to finding these mean differences between groups, we examined the distribution of Embellishment scores to determine the optimal degree of separation between confabulators and nonconfabulators. We obtained a hit rate of 69%.

The groups did not differ significantly in terms of the conventional MFD error score of Graham and Kendall (1960) (for confabulators, $M = 16.7$,

$SD = 14.2$; for nonconfabulators, $M = 13.8$, $SD = 9.0$). These values reflect considerable perceptual-motor impairment. This conventional MFD error score was positively correlated with the Embellishment score, $r(30) = .63$, $p < .001$.

The confabulators and nonconfabulators were practically identical in overall memory functioning as measured by the Wechsler Memory Scale. Means, not age corrected, for the confabulators and nonconfabulators, respectively, were 36.8 ($SD = 11.0$) and 36.2 ($SD = 7.7$). These values corresponded to a Wechsler Memory quotient of 79 and indicated that both groups had significant memory impairment.

In this investigation we began with a somewhat concrete, but hopefully, operational definition of confabulation in the real world. Our impression of a relationship between the tendency to confabulate in the real world and to embellish abstract design reproductions was borne out. Two groups of patients sharing the common characteristics of general memory and perceptual-motor impairment were distinguishable on the basis of a specific type of error production, that is, embellishment. This was true for both brain-damaged and schizophrenic patients and was related to a tendency to confabulate in their real-world interactions with hospital staff personnel. Results suggest that confabulation, as defined in this study, has perceptual, spatial, and motor correlates as well as the well-recognized deficit in verbal behavior.

Role of Self-instruction and Self-reinforcement in the Modification of Impulsivity

Wilbur J. Nelson, Jr., and John C. Birkimer
University of Louisville

This study sought to determine which components of a previously successful training procedure are necessary in modifying children's impulsivity. Forty-eight impulsive second and third graders of both sexes were used as subjects. Changes in errors and response latencies on Kagan's Matching Familiar Figures Test were used as criteria. Subjects were divided into four groups: (a) self-instruction (SI); (b) self-instruction/self-reinforcement (SI/SR); (c) attention control; and (d) assessment control. Only SI/SR subjects had significantly reduced errors and significantly increased latencies ($p < .001$). Results indicate that self-reinforcement is a necessary aspect of training in the modification of impulsivity.

Training in self-verbalization procedures has been applied to a variety of target behaviors, such as impulsivity (Meichenbaum & Goodman, 1971). In this study, subjects were taught to change their private speech as a strategy for modifying their impulsive behavior. However, little attention was given to the actual components of the self-verbalizations that were used. Thus, both self-instructive (e.g., "draw the line down, down") and self-reinforcing (e.g., "good") components were included. Thoresen and Mahoney (1974) have drawn a distinction between these categories of verbal behavior, thus producing uncertainty as to how the obtained results are to be interpreted.

The purpose of this research was to investigate the effect of self-instruction alone, in addition to the effect of a combination of self-instruction and self-reinforcement, on an impulsive response style. Thus, the design provided a test of whether both components were necessary to produce a change. Since the Matching Familiar Figures Test (MFF) has traditionally been used as a measure in this area, it was used in the present study as a pretest and a posttest. Treatment effects were determined by changes in number of errors committed and latencies to response.

The 48 subjects were black children, both males and females, enrolled in the second and third grades of a public school. An MFF pretest was used to identify the impulsive children from an initial total of 140. Subjects were randomly assigned to each of four training groups. For children in the self-instruction (SI) group, the ver-

balizations were composed of self-instruction alone, whereas subjects in the self-instruction/self-reinforcement (SI/SR) group received a combination of self-instruction and self-reinforcement. The training techniques were similar to those used by Meichenbaum and Goodman (1971). The no-self-verbalization controls received treatment identical to that of the experimental subjects but without self-verbalization training, and the assessment controls were given only the pretest and the posttest.

Simple main effects analyses of variance indicate that SI/SR children made significantly fewer errors, $F(1, 44) = 15.16$, $p < .001$, and had a significant increase in latency to response, $F(1, 44) = 13.20$, $p < .001$, from pretest to posttest MFF. No significant changes were revealed for subjects in any of the other conditions. These results are in agreement with those obtained by Meichenbaum and Goodman (1971). However, the present findings demonstrate that the emission of self-instruction alone does not produce the same results that were obtained in the earlier study. These data provide clear-cut support for the inclusion of self-reinforcement training as a component in cognitive self-instruction packages designed to modify children's impulsivity. Further research is needed to determine whether the self-reinforcement aspect is equally critical in modification of other types of behavior and skills.

The Palmar Sweat Index as a Function of Repression-Sensitization and Fear of Dentistry

Charles E. Early and Ronald A. Kleinknecht
Western Washington University

This study investigates the relationship between the repression-sensitization dimension and palmar sweating in response to simulated dental threat stimuli (drill sounds). Sensitizers were found to be more physiologically aroused than were repressors during a brief relaxation period and during a presentation of drill sounds but not during initial or final measurements. Sensitizers also reported being more fearful of dentistry than repressors. These results are seen as consistent with Mischel's social-learning formulation of repression-sensitization in terms of differential attention to threatening stimuli and contrary to repression hypotheses.

Physiological response to threatening situations is highly variable and often shows low to moderate correlations with behavioral or self-report measures. The present study was designed to investigate an individual difference variable, repression-sensitization, which is theoretically related to patterns of response to threat and which might serve to account for variability in physiological response.

Lazarus and Alfert (1964) found consistent with repression hypotheses that repressors, who reported less arousal to threatening movies than did sensitizers, showed greater levels of skin conductance response.

The Palmar Sweat Index (PSI), shown to covary with skin conductance, was used in this study as the measure of physiological arousal in response to simulated dental drill sounds (threat stimulus). Sixty female undergraduates were individually brought into the experimental room where they completed the Byrne Repression-Sensitization (R-S) scale. They were seated in a reclining chair, and the first PSI measure was taken. Next, they listened to a 5-min tape recording of relaxation instructions, designed to reduce arousal associated with the experimental setting, followed by the second PSI. Then on an alternating basis, subjects listened to one of two 15-sec tape recordings: one

with sounds of an actual dentist's drill and one of a child's windup toy car, which simulated the whining sound of a dentist's drill. Subjects were instructed to think of the respective tapes as a dentist's drill or a windup toy. At the end of each tape, the third PSI was taken. Following a brief question period, subjects were told the session was over, and the fourth PSI was taken. Before leaving, subjects completed a 20-item dental fear survey to be correlated with R-S scores.

PSI responses were analyzed using a mixed analysis of variance, with two levels of repression-sensitization (median split) and two sounds (drill or car), with repeated measures at the four points designated above. A significant main effect for repression-sensitization was found showing sensitizers to be more physiologically responsive than repressors, $F(1, 56) = 6.44, p < .05$. Since our interest was in the differential physiological response of repressors and sensitizers to the various conditions, responses were analyzed at each of the four measurement points. This analysis showed sensitizers to be more responsive than repressors during relaxation and during presentations of sounds but not on the initial or final measurement.

A significant trials effect, $F(3, 148) = 17.64, p < .01$, and a Trials \times Stimulus Group interaction, $F(3, 168) = 3.62, p < .05$, were also found. Analysis of the interaction showed that subjects who heard the drill gave greater responses on Trial 3 than on the other trials (which is to be expected, since that was the only trial on which different stimuli were presented).

The fact that sensitizers showed greater physiological responsiveness during both relaxation and threat conditions than repressors is seen as contrary to the repression hypothesis and the Lazarus and Alfert (1964) data. Further, subjects' self-

This research was partially supported by U.S. Public Health Service Grant DE04014, awarded to the second author by the National Institute of Dental Research.

Charles Early is now at the Department of Educational Psychology, Pennsylvania State University.

Requests for reprints should be sent to Ronald Kleinknecht, Department of Psychology, Western Washington University, Bellingham, Washington 98225.

reports appeared to be consistent with their physiological response as evidenced by a moderate but significant correlation of .38 between the dental fear survey and repression-sensitization, suggesting that repressors also report being generally less fearful of dentistry than sensitizers. These data would seem to be in accord with Mischel's (1976) reformulation of the repression-sensitization dimension as reflective of individual differences in learned patterns of attending to or avoiding potentially threatening stimulation, a process that could reasonably be expected to affect physiological responsiveness. An individual difference dimension

such as repression-sensitization might well serve to account for some of the observed variance in physiological responsiveness in fear research.

Effects of "Status Sets" on Rotter's Locus of Control Scale

Kay M. Davidson and Kent G. Bailey
Virginia Commonwealth University

Subjects were given sets based on varying levels of social class to determine the susceptibility of Internal-External Locus of Control Scale (I-E) scores to situationally induced frames of reference. College students ($N = 90$) took the I-E scale twice: once while playing the role of a person who had just been hired for one of six ranked occupations and once from their own frame of reference. "In-role" I-E scores revealed the expected positive relationship between levels of status and internality, and these scores differed from the subject's "out-of-role" normal responses. Present results are in accord with recent findings that the I-E scale may be subject to faking and situational effects.

It was recently reported (Deysach, Hiers, & Ross, 1976) that "internal" and "external" instructional sets affected Internal-External Locus of Control Scale (I-E) scores, and, further, scores so obtained differed from those reflecting the subject's own personal beliefs. Add to this the consistent positive empirical relationship between social status and internality (Rotter, Chance, & Phares, 1972), and the question of "faking good" on the I-E scale arises. The present study investigated how well a group of subjects could approximate the empirically established relationship between I-E scores and status. The following hypotheses were evaluated: (a) Groups of subjects given different instructional sets based on varying levels of status can discriminate between items on the I-E scale such that scores will become progressively more internal as status increases; (b) I-E scores obtained under these circumstances will differ from the subject's "normal" scores.

Ninety subjects (65 males and 25 females) were tested, representing six ranked status groups of 15 subjects each. Status levels were derived from a list of 90 occupations previously ranked according to prestige (Hodge, Siegel, & Rossi, 1964). The six jobs, from lowest to highest status, were Level 1, clothes presser; Level 2, grocery checkout clerk; Level 3, bookkeeper; Level 4, assistant personnel manager; Level 5, civil engineer; and Level 6, U.S. representative to Congress. A 50-word description was written about each job to include information about the job holder's salary, educational level, and age. Each subject took the I-E scale while imagining himself or herself in the assigned status role, and immediately thereafter retook the scale from his or her own perspective.

Requests for reprints and for an extended report of this study should be sent to Kay M. Davidson, Department of Psychology, Virginia Commonwealth University, 800 West Franklin Street, Richmond, Virginia 23284.

Analysis of variance revealed that status sets had a strong effect on subjects' I-E scores "while in the role," $F(5, 84) = 26.34$, $p < .001$. I-E scores were clearly inversely related to levels of status. Only Status Level 5 (civil engineer) deviated from a perfect negative relationship, and even then the deviation was not great. Means across the six status levels, going from clothes presser to U.S. representative were 19.50, 17.93, 13.36, 8.53, 9.93, and 5.30. Analysis of variance on the "role" versus normal score differences also proved to be highly significant, $F(5, 84) = 27.43$, $p < .0001$. Difference score means were 11.24, 9.73, 3.86, -4.60, -3.33, and -8.83 across the six status levels, and a multiple comparisons procedure revealed that pairwise combinations were significant at the extremes but not in the middle ranges and adjacent status categories. At extreme status levels, then, a reverberating effect occurred whereby role playing an external role led to internal self-scores and role playing an internal role led to external self-scores.

The above findings indicate that subjects can assume an assigned status role and then produce I-E scores congruent with that role. Further, within-role and normal self-scores tended to differ in a way that suggested a role versus self social-comparison process that raises interesting possibilities for future research.

Effects of Model Status and Juvenile Offender Type on the Imitation of Self-reward Criteria

T. John Akamatsu and Parvis A. Farudi
West Virginia University

To explore variables that could facilitate the application of modeling to the treatment of juvenile delinquents, the effects of model status and offender type on the imitation of self-reward criteria were examined. Immature-inadequate and gang-oriented offenders viewed videotapes of models who were either stringent or liberal in self-reward criteria and who were either staff members or peers. Subjects who viewed the liberal model rewarded themselves significantly more than subjects who viewed the stringent model. Significant interactions involving model status and observer type suggest that such factors should be considered in the development of treatment programs.

In the present study the effects of both model status and offender type were examined in an attempt to identify variables that might be of importance in maximizing the effectiveness of modeling approaches with juvenile offenders. The imitation of self-reward criteria was chosen for study because of consistent previous results (e.g., Thelen & Fryrear, 1971) and because this behavior was thought to be relevant to the treatment of juvenile offenders. In addition, Kuncle and Thelen (1972) found that stringent self-reward criteria resulted in improvement on actual task performance, an intriguing finding that warrants replication.

Forty-eight male subjects were exposed to a videotape of either a male adult or peer model who adopted either stringent or liberal self-reward criteria for his performance on a pursuit rotor task. Two types of juvenile offenders were chosen for inclusion in the study based on the system of Quay and Parsons (Note 1): the Behavior Category 1 (BC-1, immature-inadequate) type characterized by inability to cope in a complex world, incompetence, and immaturity; and the Behavior Category 4 (BC-4, socialized-subcultural) type characterized by having bad companions, engaging in gang activities, and being accepted by a delin-

quent subgroup. It was predicted that subjects would imitate the self-reward criteria of the model whom they observed and that model status and offender type would interact. That is, subjects from the immature-inadequate group would be more influenced by the adult model, and subjects from the socialized-subcultural group would be more influenced by the peer model. It was further predicted that exposure to the stringent model would result in better performance on the experimental task.

The procedure was an adaptation of that used by Thelen and Fryrear (1971). Subjects were tested individually, were instructed that they would be participating in an arm-coordination task, and were told that the easiest way to explain how the test worked was to show them a videotaped demonstration. Subjects were then shown one of the four videotapes. After viewing the tape their attention was directed to a chart containing normative information. They were informed that they could take a token that was worth a nickel whenever they thought they deserved it. Subjects received the following predetermined scores on the six test trials: 6, 7, 8, 8, 7, and 9.

The mean number of tokens taken by subjects on trials in which scores of 6 or 7 were obtained was the dependent measure. Preliminary analysis indicated that no significant effects could be attributed to race of subject, so this variable was collapsed. A 2 (stringent-liberal) \times 2 (adult or peer model) \times 2 (behavior category type) analysis of variance was carried out on these data. The analysis revealed a main effect for reward criteria, $F(1, 40) = 41.00$, $p < .0001$. Subjects exposed to the stringent model took fewer rewards

This research was supported by a grant from the West Virginia University Foundation. The authors are grateful to Helene Cavior and Lawrence E. Melamed for their assistance in this project.

($M = .625$) than subjects exposed to the liberal model ($M = 2.33$).

The analysis of variance also revealed a significant Reward Criteria \times Model Status \times Behavior Category Type interaction, $F(1, 40) = 4.122$, $p < .05$. Inspection of the means revealed that as predicted, BC-1 subjects showed greater imitation of the staff models than peer models under both stringent and liberal conditions. The reverse was true for BC-4 subjects. Although the differences were in the predicted directions, post hoc Newman-Keuls analyses revealed that they were not significant. The significant interaction was a function of no difference in the imitation of stringent and liberal peer models by BC-1 subjects. Similar comparisons for BC-4 subjects and for BC-1 subjects who were exposed to staff models were all significant ($p < .01$).

Mean time on target for the six pursuit rotor trials was analyzed with a 2 (stringent vs. liberal) \times 2 (staff vs. peer) \times 2 (BC 1 vs. BC 4) \times 6 (trials) repeated measures analysis of variance, which revealed a main effect for reward criteria. Subjects exposed to the stringent models ($M = 5.70$) performed significantly better than subjects exposed to the liberal models ($M = 4.02$), $F(1, 40) = 6.91$, $p < .02$. A main effect for behavior category type was also detected such that BC-4 subjects performed better than BC-1 subjects ($M = 5.56$ vs. 4.17), $F(1, 40) = 4.73$, $p < .03$. A significant interaction between model status and behavior category type was also detected, $F(1, 40) = 8.122$, $p < .01$. Newman-Keuls analyses revealed that BC-1 subjects who observed the staff model ($M = 3.22$) performed significantly more poorly than BC-1 subjects who observed the peer model ($M = 5.11$, $p < .05$) and BC-4 subjects who observed the staff model ($M = 6.45$, $p < .01$).

The results of the study confirm that self-reward criteria are imitated by juvenile offenders even when less stringent norms are provided. The importance of model status and juvenile offender type in determining the amount of imitation shown is at least partially supported by the data. Differences in imitation as a function of these variables were found as indicated by the significant three-way interaction. Although differences were in the predicted directions, they were not significant. It may be that the restricted range of possible responses (0-3) resulted in a ceiling effect that obscured differences.

A differential susceptibility to staff versus peer models among BC-1 subjects is supported by the data. For these subjects even the potent reward criteria manipulation did not affect imitation of the peer model. It would appear that the staff

model was a more salient source of information for BC-1 subjects than was the peer model.

The results of the analyses on the pursuit rotor scores confirm the finding of Kuncze and Thelen (1972) that observation of a stringent model results in better task performance. Thus, modeling procedures do seem to have effects that go beyond the simple replication of the observed behavior. Greater motivation to perform well, or greater attention to the task at hand, might result from exposure to a stringent model.

The finding of better performance among BC-4 subjects is not too surprising, since on a common-sense level one might expect such subjects to perform better on motor tasks than immature-inadequate types. Involvement by BC-4 types in a broader variety of activities or competitive interaction with peers in sports or games could result in superior performance.

The interaction of model status and behavior category type found in the present study further supports the notion of differential susceptibility to staff and peer model influences among offender types. The BC-1 subjects performed more poorly in the staff model condition perhaps as a function of the perceived discrepancy in abilities between themselves and the model. Such a difference was not found among BC-4 subjects.

In summary, the results of the present study have confirmed the feasibility of the application of modeling techniques to the treatment of juvenile delinquents. Both direct observational learning and indirect motivational effects have been demonstrated. Results concerning the effects of model status and offender type, although not conclusive, suggest that consideration of such variables may be of importance in creating more individualized and maximally effective treatment programs.

The purpose of the study was to investigate the factor structure and scale reliabilities of Gough's Adjective Check List (ACL) and to assess their stability over time. Employees in a community mental health center completed the ACL twice, separated by a 1-year interval. After each administration, separate factor analyses were computed. All scales had highly significant test-retest reliabilities. Five factors emerged in each analysis, two of which accounted for about 55% of the common variance. Repetition of factor analysis at two different times resulted in a more stable factor structure than did the usual method of single-time analysis.

The purpose of this research was to investigate the factor structure of Gough's Adjective Check List (ACL; Gough & Heilbrun, 1965) and to assess the stability of this structure over time. Since Gough's original article (Gough, 1960), the ACL has been widely used in personality assessment.¹ Recent studies illustrate the diversity of its application (e.g., Patrick, Zuckerman, & Masterson, 1974; Sowa & Lutter, 1974).

In spite of its popularity, few studies have been done to assess the internal characteristics of the ACL's 24 scales. In factor-analytic investigations, Parker and Megargee (1967) found 4 factors and Scarr (1966) found 10. Neither of the studies provided evidence about the stability of those factors over time. The only available information about scale reliabilities is provided by Gough and Heilbrun (1965).

Respondents were 71 professional employees in a community mental health center. Of the 71, 35 were males. Their average age was 36.2 years, and their average number of years of formal

education was 16.9. Sixty-two of the participants were white, and the rest were distributed across various minority groups. As part of a larger project, the respondents completed the ACL twice, at approximately a 1-year interval.

After each administration, separate factor analyses, using varimax rotations, were computed on the *T* scores for the 24 ACL scales. The two resulting factor structures were compared by calculating a coefficient of congruence (Harman, 1967, pp. 269-272) for each scale score. Test-retest reliabilities were also calculated for each of the 24 scales.

The scales comprising each of the five factors and their loadings on the factors for each administration are given in Table 1. To be included in the factor, the scale had to have a loading greater than an arbitrarily decided on .40 in each of the two analyses. Eighty-one percent of the total communality was accounted for by each of the five factors for each administration. All of the coefficients of congruence were significant beyond the .001 level.

Test-retest correlations (ranging from a low of .51 to a high of .86, $M = .71$) for each of the 24 ACL scales were significant beyond the .001 level. These reliabilities were all greater than those reported in the ACL manual for adult males (6 months between testings) and for medical students (5½ years between testings).

The data clearly indicate the primacy of Factors 1 and 2. Even though Factors 3, 4, and 5 are also replicable and interpretable, they account for less variance in the results than do

Order					.78	.79				
Heterosexuality							.60	.62		
Counseling readiness							-.64	-.67		
Libility									.47	.63

Note. t_1 = Time 1; t_2 = Time 2.

Factors 1 and 2. Factor 1 seems to reflect "self-confidence and competency." Factor 2 reflects "conventional sociability." Factor 3 appears to reflect an "organized industriousness" coupled with desire for achievement, Factor 4 reflects "lack of anxiety and self-doubt," and Factor 5, "instability or changeability."

The results of the present study do not readily allow comparison with other factor-analytic studies. The samples in previous studies differ, and there is no report in these studies of attempts to assess stability of the factors across time. The Parker and Megargee (1967) study is informative, however, since these authors obtained four factors that are quite similar to the four found here, despite lack of sample similarity and method of administering the instruments. Of the 13 scales in their Factor 1, 4 are present in our Factor 1. Seven of their Factor 1 scales are present in our Factor 2, and 2 are present in our Factor 4. Parker and Megargee's Factor 2 includes 7 scales, all of which are found in our Factor 1. In the Parker and Megargee study, about 66% of the common variance is accounted for by the first two

factors; in the present study, about 55% of the total variance is accounted for by the first two factors.

The data are highly encouraging for users of the ACL. The fact that every scale had a high test-retest reliability increases one's confidence in their validity potential. It appears that whatever the ACL scales measure, they do it consistently. This stability also appears in the factor structure, at least for this sample. If such findings were reported for other samples, the evidence for the utility of the ACL as a reliable measurement device would be enhanced.

The technique of repeated factoring at two different points in time results in a more stable factor structure than does the usual method of single-time analysis. One possible reason for differences in the results reported here and those reported by Parker and Megargee (1967) is that in this study many scales that loaded in the first administration failed to load in the second administration. It would be informative to refactor the Parker and Megargee data using a randomly selected hold-out sample for cross-validation. In light of the many scales that "drop out" during

cross-validation, it would not be surprising to find that such an analysis would provide data more consonant with those reported here. The fact that certain scales did replicate for the same sample across time in this study lends strong support for continuing to cross-validate factor structures for this and other personality diagnostic instruments.

The Seashore Tonal Memory Test as a Neuropsychological Measure

Carl B. Dodrill and Sureyya S. Dikmen

Department of Neurological Surgery
University of Washington School of Medicine

The sensitivity of the Tonal Memory Test to impaired brain function was evaluated and compared with that of Halstead's Neuropsychological Battery and the Trail Making Test. Neurologic subjects consisted of 102 individuals with histories of head trauma or epilepsy, and control subjects consisted of 68 individuals without histories of neurological problems. In general, the Tonal Memory Test differentiated the normal and neurologic individuals on either a subject-by-subject or group-by-group basis as well as did the other neuropsychological measures, and without excessive overlap with them.

Few studies have been reported that have utilized the Seashore Tonal Memory Test in the investigation of the behavioral correlates of brain lesions. In probably the most extensive report of this type, Milner (1962) used it in evaluating the effects of temporal lobectomy for epilepsy. Although Milner's study and others have suggested that the Tonal Memory Test may be useful in the evaluation of brain-related conditions, none have attempted a formal evaluation of the measure. The goal of this study was to establish the discriminative value of the test in differentiating between normal and neurologic patients and to compare it with the other measures in the neuropsychological battery originated by Halstead and developed by Reitan.

The normal controls included 68 individuals on whom extensive neurological histories revealed no neurological problems or events that may have resulted in such problems. They were solicited from a variety of community agencies and not from any patient population. The mean age of the group was 27.22 years ($SD = 10.07$), and the mean education was 12.28 years ($SD = 1.29$).

This project was supported by National Institutes of Health contract numbers NO1-NS-0-2281 and NO1-NS-2-2326 and Research Grant NS04053 awarded by the National Institute of Neurological and Communicative Disorders and Stroke, U.S. Public Health Service, Department of Health, Education, and Welfare. Sureyya Dikmen is affiliated with the University of Washington Child Development and Mental Retardation Center.

Requests for reprints and for an extended report of this study should be sent to Carl B. Dodrill, Epilepsy Center (ZA-50), Harborview Medical Center, Seattle, Washington 98104.

The neurologic group consisted of 57 individuals with seizure disorders and 45 individuals with head injuries. Each of these subgroups was diversified with respect to type and characteristic of the neurological problem in question, but a positive diagnosis of the problem was made in each instance. The mean age of the total group was 26.45 years ($SD = 10.52$), and the mean education was 12.33 years ($SD = 1.85$).

The Seashore Tonal Memory Test (Seashore, Lewis, & Saetveit, 1960) consists of 30 pairs of tonal sequences including 10 items each of three, four, and five note spans. One note is different in the two sequences of each pair, and the subject must identify that note by number. The final score represents the number of items correctly completed. The other tests in the neuropsychological battery are well-known.

The results of the study are summarized in Table 1. The tests are arranged in this table in order from that producing the largest t value to that producing the smallest. The classification of individual subjects was done on the basis of pre-established cutoff scores for all measures but the Tonal Memory Test. For this measure, a cutoff score between 21 and 22 correct answers produced the largest number of correct individual classifications. Using either the group-by-group or subject-by-subject discriminative procedures, the Tonal Memory Test did as well as did the typical test in the battery in distinguishing between normal and neurologic patients.

Several findings from this study are worthy of comment. First, the Tonal Memory Test appeared to be somewhat better than the Rhythm Test in differentiating between normal and neurologic subjects. This may be due in part to the fact that it is technically more adequate in construction, since

Table 1
Data for Normal and Neurologic Patients on All Test Variables in Order of Efficacy

TPT—Memory	8.06	1.20	7.00	1.91	4.07**	49
Category	32.84	18.86	47.25	27.06	-3.82*	55
Rhythm	27.00	2.20	25.24	3.44	3.75*	61

Note. TPT = Tactual Performance Test.

^a *n* = 68.

^b *n* = 102.

* *p* < .001 (*t* ≥ 3.35).

** *p* < .0001 (*t* ≥ 3.99).

it has a lower chance score (8) in comparison with the Rhythm Test (15) and therefore a greater range in scores. Its greater difficulty also tends to promote a broader range of scores and greater differentiation between groups.

Although the effectiveness of the Tonal Memory Test in the classification of individual subjects was very modest, we observed that the classification of the other better known tests was usually no better and sometimes somewhat worse (e.g., Category). In addition, in studies in which there was a distinctively better classification of subjects (e.g., Reitan, 1955), we observed that most of the neurologic patients had grossly discernible evidence of tissue damage to the cerebral hemispheres. A detailed evaluation of our patients is not likely to routinely show such grossly discernible alterations in brain structure. They did show very definite signs of impaired brain functions, however. Thus, our neurologic group might be better described as showing signs of "brain impairment" rather than "brain damage," and it is possible that the poorer discrimination by some of the measures found by us may be due, at least in part, to this difference.

With respect to overlap between the Tonal Memory and other tests, the median correlation was .26 for normal controls and .49 for neurologic patients. This appears to be no higher than the correlations of the other tests among themselves.

The apparently superior discriminating ability

of the Tapping Test is explainable at least in part by the fact that 47 patients were taking Dilantin at the time of testing. Dodrill (1975) has shown that this drug has a fairly specific impact on motor performance, and the striking intergroup differences likely thus reflect both impaired brain functions and drug effects.

Overall, the Seashore Tonal Memory Test is a short measure that differentiates normal from neurologically impaired individuals at levels of statistical significance that are consonant with those already used in the neuropsychological battery, and it does so without undue overlap with these measures.

Relationships Between Dimensions of Anxiety and Sensation Seeking

Barry R. Burkhart, Raymond M. Schwarz, and Samuel B. Green
Auburn University

To determine more precisely the relationships between the general dimensions of sensation seeking and anxiety, 242 undergraduates (130 males, 112 females) completed the Sensation Seeking Scale (SSS) and the S-R Inventory of General Trait Anxiousness (S-R GTA). The intercorrelations among the five scales from the SSS and the four scales from the S-R GTA were computed and compared to theoretical predictions. In general, the empirical findings were consistent with rational and theoretical notions. The majority of the correlations were negative, with the strongest relationship existing between anxiety in physically dangerous situations and sensation-seeking needs. However, the marked variation in the intercorrelations, ranging from moderately negative to low positive, is interpreted as supporting the necessity of multi-dimensional measures of both the anxiety and sensation-seeking constructs.

Recent research has established that a comprehensive theory of motivation must incorporate both tension reduction and stimulus seeking as complementary, multidimensional constructs (McReynolds, 1971). Development of theory and research in this area clearly would be enhanced by the specification of the empirical relationships between the various dimensions of anxiety and stimulus seeking. Segal (1973) reported such data for the Sensation Seeking Scales (SSS; Zuckerman, Note 1) and the S-R Inventory of Anxiousness (Endler, Hunt, & Rosenstein, 1962). As predicted, most of the correlations between the dimensions of sensation seeking and specific anxiety stimulus situations were negative, although they varied greatly in magnitude. The strongest negative relationship occurred between anxiety responses in situations involving physical danger and sensation seeking.

The present study was conducted to extend the results reported by Segal (1973) by attempting to determine the relationships between the general dimensions of sensation seeking and anxiety. The instruments used were the SSS and an extensive revision of the S-R Inventory, the S-R Inventory of General Trait Anxiousness (S-R GTA), which was constructed to rectify the psychometric deficiencies and limited generalizability of the S-R Inventory of Anxiousness (Endler & Okada, 1975). Unlike the older version, which used 11 specific situations, the

S-R GTA is composed of four general stimulus situations: interpersonal, physically dangerous, new or ambiguous, and routine situations. The SSS is composed of five separate factorially derived scales: the General scale, Thrill and Adventure Seeking (TAS), Experience Seeking (ES), Disinhibition (Dis), and Boredom Susceptibility (BS).

The subjects for this study were 242 undergraduates, both males ($n = 130$) and females ($n = 112$), at Auburn University. Each student was asked to complete the SSS and the S-R GTA. Initially, intercorrelations were computed separately for males and females between the four scales of the S-R Inventory and the five SSS scales. In light of the fact that just 1 of the 20 pairs of correlations differed significantly for males and females and due to space limitations, only the correlational matrix for males and females combined is presented.

The results of the correlational analysis are presented in Table 1. The magnitude and the sign of the correlations between the SSS scales and the S-R Inventory subscales varied from moderately negative for Situation 2 (physical danger) to low positive for Situation 4 (innocuous-routine), with Situation 3 (ambiguous-new) and Situation 1 (interpersonal) falling between the two extremes. This ordering of the correlations is rationally appealing. Individuals who prefer to participate in sensation-seeking activities tend not to be anxious in physically dangerous situations. On the other hand, people who are anxious in innocuous, routine situations may be expected to seek sensation-producing experiences. (It should be noted that the positive

Table. 1
Intercorrelations Between Sensation-Seeking Factors and Subscales of the S-R Inventory of General Trait Anxiousness

SSS factor scale	S-R Inventory subscale			
	Interpersonal	Physical danger	Ambiguous	Innocuous
General SSS	-.11	-.30***	-.23***	.18**
Thrill and adventure seeking	-.09	-.37***	-.18**	.10
Experience seeking	-.14*	-.31***	-.23***	.20***
Disinhibition	-.03	-.18**	-.09	.17**
Boredom susceptibility	-.15*	-.22***	-.25***	.24***

Note. SSS = Sensation Seeking Scale.

* $p < .05$.

** $p < .01$.

*** $p < .001$.

relationship between sensation seeking and anxiety arousal in routine situations was significant only for females.) Ambiguous-new situations and interpersonal situations were not as clearly related to sensation seeking, although the former is more similar to the physically dangerous situations than the latter. The correlational pattern supported this continuum.

These results partially replicate the findings of Segal (1973). Again, the majority of the correlations were negative, with the largest ones associated with situations that involved physical danger. However, these results also suggest that differential relationships exist for different dimensions of anxiety and sensation seeking. This theoretically consistent variation makes a compelling case for the necessity of multidimensional measures of both constructs and provides valuable evidence of the construct validity of their measures.

Psychotherapy Process Variables Distinguishing the "Inherently Helpful" Person from the Professional Psychotherapist

Beverly Gomes-Schwartz and Joseph M. Schwartz
Vanderbilt University

Therapeutic hours conducted by analytically oriented, experientially oriented, and nonprofessional ("inherently helpful" college professors) therapists were rated along eight process dimensions—therapist exploration, therapist directiveness, feeling attention, task orientation, therapeutic relationship, patient exploration, patient negativism, and patient psychic distress. Between-group differences were obtained on six of the eight dimensions. Only patient negativism and patient exploration failed to yield significant effects. These results substantially replicated the findings of previous analogue investigations.

Although nonprofessional therapists often assume major responsibilities for mental health care, little is known about how the untrained but "inherently helpful" nonprofessional conducts therapy. In simulated interviews, untrained "therapists" tend to make directive interventions rather than exploring patients' feelings or experiences (cf. D'Augelli, Danish, & Brock, 1976). Nonetheless, in similar mock interactions, nonprofessionals (e.g., untrained college students; Pope, Nudler, VonKorff, & McGee, 1974) were as warm, genuine, and empathic as experienced therapists. Indeed, the interviewees felt more accepted and were less anxious in interviews with nonprofessional, as opposed to professional, therapists.

Previous discussions of professional-nonprofessional differences have not taken into account the effects of therapists' theoretical orientations. However, evidence from surveys of therapists' self-described techniques (cf. Sundland & Barker, 1962) and from studies of therapists' responses in analogue interviews (cf. Strupp, 1960) suggests that analytically oriented therapists rely on interpretive techniques, whereas Rogerian or experiential therapists focus on establishing warm, personal relationships.

This research was supported by National Institute of Mental Health Grant 20369. The contributions of H. H. Strupp, principal investigator, and D. Hartley, S. Hadley, and G. Blackwood are gratefully acknowledged.

Requests for reprints and for an extended report of this study should be sent to Beverly Gomes-Schwartz, who is now at Department of Psychology, McLean Hospital, Belmont, Massachusetts 02178.

Although the activities of novice therapists in simulated interactions may be similar to those of nonprofessionals counseling genuinely disturbed clients, generalization of findings from analogue investigations must be viewed with caution. The present study was undertaken to determine whether previous findings would be replicated in the actual therapeutic interactions of analytic, experiential, and untrained therapists.

The patients were 25 unmarried, male college students with elevated scores ($T > 60$) on Minnesota Multiphasic Personality Inventory Scales 2, 7, and 0 who were participating in a psychotherapy outcome study. On a rotational basis, 8 patients had been assigned to analytic therapists (3 male psychiatrists, M experience = 29.0 years), 7 to experiential therapists (2 male psychologists, M experience = 19.5 years), and 10 to alternate therapists. The 6 alternate therapists were experienced male professors (M years since PhD = 18.0) identified by university administrators, faculty, and students as teachers who were frequently approached by students for personal counseling. Although the professors had no formal psychotherapy training, they were recognized in the academic community as inherently helpful people.

Two advanced clinical psychology graduate students independently rated videotapes of each third therapy session on the Vanderbilt Psychotherapy Process Scale (VPPS; Strupp, Hartley & Blackwood, Note 1). This 84-item Likert-type scale was developed from earlier work by Orinsky and Howard (1967) to rate psychotherapy process from the perspective of a clinical observer. Eight subscales derived from the instrument were internally consistent (average co-

efficient $\alpha = .82$) and were rated with satisfactory agreement (average interrater $r = .82$). Two scales tapped therapist factors—Therapist Exploration and Therapist Directiveness. Three scales measured patient dimensions—Patient Exploration, Patient Psychic Distress, and Patient Negativism. Three scales gauged combined patient and therapist contributions—Feeling Attention, Task Orientation and Therapeutic Relationship.

Based on previous analogue findings, the following differences among treatment groups were hypothesized and tested via univariate F tests and Newman-Keuls comparisons ($p < .05$ significance level):

1. Analytic therapists and their patients were expected to engage in greater exploration of psychodynamics than either experiential or alternate dyads. The predicted effect was obtained on ratings of Therapist Exploration, $F(2, 22) = 6.00, p < .01$. Analytic therapists received higher scores than experiential or alternate therapists. Although differences among the groups on Patient Exploration were in the predicted direction, they failed to reach significance, $F(2, 22) = 2.07, p = .15$.

2. Alternate therapists were expected to use more directive interventions (e.g., concrete suggestions) than either professional group. Although overall differences on Therapist Directiveness were significant, $F(2, 22) = 3.56, p < .05$, only analytic therapists were less directive than alternates.

3. Analytic and experiential dyads were expected to focus on important therapeutic issues, particularly examination of patients' feelings, to a greater extent than alternate dyads. On both Task Orientation and Feeling Attention, overall differences were significant, $F(2, 22) = 4.76, p < .05$, and $F(2, 22) = 5.82, p < .01$, respectively. Analytic and experiential pairs received higher scores than alternate pairs on both dimensions.

4. Experiential and alternate therapists were expected to maintain friendlier, more open relationships with their patients than were analytic therapists. Ratings of Therapeutic Relationship yielded a significant overall effect, $F(2, 22) = 10.86, p < .001$, and the predicted differences among groups.

5. No differences among groups in patients' resistance and expression of hostility were anticipated, and no differences on Patient Negativism were obtained ($F < 1$).

6. Patients seen by alternate therapists, as opposed to professionals, were expected to manifest less anxiety in the session. Although a sig-

nificant overall effect was obtained on ratings of Patient Psychic Distress, $F(2, 22) = 4.29, p < .05$, only patients seen by analytic therapists were more distressed during the session than those seen by alternate therapists.

The findings in this study are largely consistent with previous analogue results. Congruent with their theoretical preferences, analytic therapists explored psychodynamics, whereas experiential therapists offered warmth, empathy, and genuineness. In contrast to the professionals who tend to focus on significant therapeutic issues, alternate therapists seemed to engage in informal conversation and advice giving. Perhaps their patients' lesser anxiety in the sessions may be attributed to the alternate therapists' reluctance or inability to examine sensitive intrapsychic or interpersonal issues.

Although the present results suggest that untrained nonprofessionals should not be used with the expectation that they offer the same services as professional therapists, no conclusions as to the effectiveness of the nonprofessionals' interventions can be drawn from these data. Indeed, patients in this study were equally satisfied with their therapist, regardless of the therapist's professional status.

Results of the ongoing Vanderbilt psychotherapy project from which the present data were derived are likely to further clarify the impact of observed variations in therapeutic approach on outcome.

"Acceptance," Values, and Therapeutic Change

Larry E. Beutler

Department of Psychiatry
Baylor College of Medicine, Houston, Texas

Stephen Pollack

University of Houston

Avis Jobe

Texas Department of Corrections, Huntsville

This article studied the role of therapist acceptance of patient values, patient acceptance of therapist values, and value persuasion on outcome among 13 psychotherapy dyads. A priori assessment of value acceptance was related to patients' perceptions of their therapists and ratings of improvement, with outcome being enhanced by selective value rejection as well as acceptance. A strong relationship ($p < .01$) was found between the patients' acquisition of their therapists' values and their ratings of improvement.

The current project was designed as an effort to evaluate psychotherapy as a social persuasion process. Hence, self-ratings of improvement and value change were assessed as influenced by (a) the therapist's ability to accept the values of the patient, (b) the patient's ability to accept the therapist's values, and (c) the amount of initial similarity between the patient and the therapist on several value and attitudinal dimensions.

Although the importance of therapist "acceptance" is well recognized in psychotherapy research, little attention has been given either to the role of the patient's ability to accept the therapist or to the possibility that some values are more important to accept than are others. In the current effort to remedy this lack, 13 second-year graduate students in clinical psychology, all having been trained in relationship/insight-oriented therapy, were used as therapists. One case was randomly selected from each therapist's caseload. The patients' ages ranged from 17 to 25 ($M = 20.5$).

Prior to beginning therapy all therapists were asked to complete a series of value questionnaires developed and described elsewhere (Beutler, Jobe, & Elkins, 1974). These scales assessed values relative to others' approval, the threatening nature of the world, God, Communism, Christianity, social laws, and premarital sexual behavior. Each scale was constructed in such a way as to derive latitudes of acceptance and rejection as well as the respondent's preferred attitude on each dimension.

After the first visit and again at the end of 12 psychotherapy sessions, patients were also assessed

on the value questionnaire. On the latter occasion patients completed another questionnaire (Wilson, Morton, & Swanson, Note 1), which was designed to assess their improvement on three dimensions: satisfaction with therapy, satisfaction with the therapist, and global improvement.

Patient and therapist compatibility on the value scale was assessed in two ways. The therapist's values were considered acceptable to the patient if the therapist-preferred position fell within the patient's latitude of acceptance. A similar strategy was used to assess the patient's acceptability to the therapist. In addition, the role of actual similarity as opposed to acceptability was assessed by calculating the number of statements separating the patient's and therapist's preferred positions on each scale.

The influence of three major independent variables on each of three outcome measures was assessed by means of a series of stepwise linear regression analyses. The results suggest that if either the therapist or the patient initially rejected their counterpart's estimate of threat in the world while accepting their views on premarital sex, satisfaction with therapy was increased. The same basic pattern also facilitated global improvement, although only insofar as the therapist's acceptance and rejection of the patient's values were concerned.

A significant correlation ($r = .76$, $p < .01$) was obtained between global improvement ratings and the degree to which patients came to acquire their therapists' attitudes across the seven scales. Apparently, adoption of a therapist's view of life facilitates a patient's sense of positive growth.

Finally, patients' attitudes toward their therapists were enhanced if they rejected their therapists' belief or disbelief in God and acquired their

Requests for reprints should be sent to Larry E. Beutler, Department of Psychiatry, Baylor College of Medicine, Houston, Texas 77030.

values. On the other hand, if the therapists reject their patients' opinions both of Christianity and approval, they also become increasingly attractive to their clients.

Although limited in generalizability, the findings have implication for ethics, training, and the practice of psychotherapy. The concomitant initial rejection of therapists' views of the world with the acceptance of their views about God and sexuality are of particular significance in demonstrating that acceptance need not be complete. Selective rejection of the therapist's values may also be important, although the dynamics of this relationship are unclear. For example, the pervasive relationship between patient-therapist initial disagreement about world threat and outcome is not clear and deserves special research attention.

Apparently, the therapist's attitude toward the patient's values has its greatest impact on the patient's feelings of growth, the patient's attitude

toward the therapist's values seems more strongly related to the development of trust and attraction, and acquiring the therapist's values facilitates general improvement.

Effect of Physical Attractiveness on Therapists' Initial Judgments of a Person's Self-concept

Stevan E. Hobfoll and Louis A. Penner
University of South Florida

The purpose of this study was to investigate the effect of a person's physical attractiveness on a therapist's initial judgment of that person's self-concept. Videotapes and audiotapes were made of interviews with attractive and unattractive males and females. Graduate students in clinical psychology rated the person they had heard (seen) as to self-concept. As hypothesized, physically attractive persons of both sexes were rated as having better self-concepts than unattractive persons. Further, the self-concept ratings of attractive females increased significantly from the audiotape to the videotape conditions, whereas the ratings of all the other stimulus persons remained the same.

Social psychological research on physical attractiveness has shown that a physically attractive stimulus person will be seen as possessing more positive personality attributes than a physically unattractive person (cf. Berscheid & Walster, 1974). Other studies have suggested that this stereotype may be more pronounced for female than for male stimulus persons. Despite the growing concern with sex role stereotypes as they may affect clinical practices (Report of the Task Force, 1975), there has been relatively little research conducted on the extent to which clinicians adhere to these societal stereotypes in their judgments of their clients.

The purpose of this study was to examine the relationship between a person's (judged) physical attractiveness and a therapist's estimate of that person's self-concept. It was hypothesized that ratings of a stimulus person's self-concept would be positively related to the stimulus person's physical attractiveness and that this relationship would be stronger for female than for male stimulus persons.

Undergraduates rated photographs of 83 of their classmates on an 11-point scale of physical attractiveness. On the basis of these ratings, the 2 most attractive males, 2 least attractive males, and a similar number of females were selected as the stimulus persons. These 8 people were interviewed, and a 10-minute audiotape or videotape of the interview was presented to 13 male

and 3 female graduate students in clinical psychology, each of whom had had at least 1 year of clinical experience. After hearing (viewing) an interview with a stimulus person, the student clinicians rated that person on a 7-point scale of self-concept. Data were analyzed via two 8×8 Latin squares, with mode of presentation as the between-subjects variable and physical attractiveness, sex, and tapes (2 stimulus persons were used in each condition) as the within-subjects variables.

Stimulus persons rated as most attractive were judged by student clinicians as having a significantly better self-concept than unattractive stimulus persons, $F(1, 91) = 349.59, p < .001$, and males were rated as having better self-concepts than females, $F(1, 91) = 8.29, p < .01$. There was a significant Mode of Presentation \times Attractiveness interaction, $F(1, 91) = 8.24, p < .01$. Although the attractive stimulus persons were rated as having better self-concepts than the unattractive people in both the audiotape and videotape conditions, the self-concept ratings of attractive persons increased significantly from the audiotape to the videotape conditions. The ratings for unattractive stimulus persons remained the same. Finally, there was a significant Mode of Presentation \times Sex \times Attractiveness interaction, $F(1, 91) = 6.309, p < .05$. Attractive females were rated as having significantly better self-concepts in the videotape condition than in the audiotape condition, but ratings of all other stimulus persons did not change.

The finding that attractive stimulus persons received higher self-concept ratings in the audiotape condition was unexpected. Explanations of this finding may lie in Berscheid and Walster's

Requests for reprints and for an extended report of this study should be sent to Louis A. Penner, Department of Psychology, University of South Florida, Tampa, Florida 33620.

(1974) argument that people judged by others as physically attractive may have more positive social experiences than unattractive persons. Thus, the higher self-concept ratings of attractive stimulus persons in the audiotape condition may have been due to these people manifesting more self-confidence and better social skills in the interview than unattractive stimulus persons. At the same time, the results of this study suggest that the student clinicians did adhere to societal stereotypes as to the relationship between physical attractiveness and the possession of positive attributes. Further, it would appear that these stereotypes exerted their

strongest influence when the stimulus person was an attractive female.

Empathy and Imagery in Avoidance Behavior Reduction

John T. Esse
University of Miami

Wallace Wilkins
University of Maine at Orono

This therapy analogue study was designed to assess the relative effects of therapist empathy and instructed imagination of hierarchy scenes on avoidance behavior reduction. Although the communication of differential therapist empathy was validated, behavior change attributable to therapist empathy was minor in comparison to the effects of imagery instructions. Imagery instructions delivered in a relatively unempathetic fashion produced as much avoidance reduction as imagery instructions delivered in an empathetic manner. Unempathetic imagery instructions also produced significantly greater avoidance reduction than the establishment of an empathetic relationship without instructed imagery exercises.

Although the efficacy of systematic desensitization, as a treatment package, has been documented, considerable controversy exists about the specific elements and the theoretical mechanisms that account for gain. Therapist empathy, defined as an ability to understand a client's experiences and communicate that understanding to the client, is also a focus of considerable debate concerning the conditions that facilitate therapeutic gain. In this study, to assess the relative contributions of imagery instructions and therapist empathy, imagery exercises were delivered with and without empathy; empathy was delivered with and without imagery instructions.

The subjects were 30 undergraduate female students who indicated "much fear," "very much fear," or "terror" on Item 39 (snakes) during a classroom-administered Fear Survey Schedule II (Geer, 1965), and who were unable to touch with bare hands a live, 3-foot (.91 m) king snake during the Behavioral Avoidance Test (BAT; Nawas, 1971). All participants in the study received credit toward partial fulfillment of introductory psychology course requirements.

The pre-BAT and post-BAT were conducted by a female experimenter, who remained experimentally blind as to the hypotheses and design of the study. Following the pre-BAT, subjects were contacted for a treatment session that lasted for a maximum of 45 minutes. All sessions were administered individually by a female graduate student after subjects were informed that "the procedure

which you are about to undergo has often been found helpful in reducing snake fear." Immediately following the treatment session, each subject completed a set of ratings, which included the 16 empathetic understanding items from the Barrett-Lennard Relationship Inventory (Barrett-Lennard, 1962), and was tested on the post-BAT.

Mechanical Imagery Procedure

The 10 members of this group received a modification of the instructed attention shift procedure, shown by Wilkins and Domitor (1973) to be effective in reducing avoidance behavior in a short period of time. The procedure was executed in a mechanical fashion that allowed little deviation from the predetermined procedure and minimized therapist empathetic reactions. The hierarchy of scenes that was presented for instructed imagination consisted of the 20 BAT steps read in the second-person present tense beginning with the least threatening and proceeding to the most threatening scene.

Empathetic Imagery Procedure

The 10 members of this group received the basic procedures of the mechanical imagery procedure (MIP) delivered in a more informal, responsive, and spontaneous manner. During the presentation of the imaginal scenes, the therapist varied the wording of the scene descriptions and the tone of her voice so as to be more responsive to the feelings that the subject appeared to be experiencing.

Empathetic Conversational Procedure

The 10 members of this group were asked to talk about feelings about snakes. There was verbal

Requests for reprints and for an extended report of this study should be sent to John Esse, who is now at Trend Community Mental Health Services, 242-B Second Avenue East, Hendersonville, North Carolina 28739.

exploration of any methods that the subject felt would be helpful in reducing her fear, and, at some point during the session, she was also asked to imagine herself approaching a snake and to describe the feelings that were aroused. Beyond this general suggestion, however, no directives were given as to what she could do to become less fearful. During the entire session the therapist attempted to be maximally sensitive to and reflective of emotional expressions.

Validation of Empathy Manipulation

Within a possible range from -48 to $+48$, mean ratings of empathetic understanding for the MIP, the empathetic imagery procedure (EIP), and empathetic conversational procedure (ECP) groups were, respectively, 1.70 ($SD = 6.147$), 21.90 ($SD = 5.466$), and 18.30 ($SD = 7.602$). An examination of specific comparisons among group means showed that significantly greater therapist empathy was communicated during the EIP than during the MIP $F(1, 18) = 60.301$, $p < .001$, and that significantly greater empathy was communicated during the ECP than during the MIP $F(1, 18) = 28.831$, $p < .001$. Statistically nonsignificant differences occurred between the EIP and the ECP groups.

Avoidance Behavior Change

Mean pretreatment BAT scores for the MIP, EIP, and ECP groups were, respectively, 8.20 ($SD = 3.259$), 8.10 ($SD = 2.378$), and 8.00 ($SD = 3.266$). Posttreatment BAT means were, respectively, 13.90 ($SD = 3.573$), 13.30 ($SD = 2.263$), and 10.10 ($SD = 5.259$). A 2 (trials) \times 3 (treatments) repeated measures analysis of variance performed on BAT scores resulted in a significant trials main effect, $F(1, 27) = 52.703$, $p < .001$, and a Treatments \times Trials interaction, $F(2, 27) = 3.558$, $p < .05$. Orthogonal comparisons of BAT change scores among the groups showed that the EIP resulted in significantly greater improvement than the ECP, $F(1, 27) = 4.495$, $p < .05$, and that the MIP resulted in significantly greater

improvement than the ECP, $F(1, 27) = 6.062$, $p < .05$. Differences between the MIP and EIP were statistically nonsignificant. The number of posttreatment MIP, EIP, and ECP subjects who actually touched the snake bare-handed (BAT Step 14; Nawas, 1971) were, respectively, 7 , 4 , and 2 .

From the pattern of results that emerged from this study, it is apparent that in comparison to the effect of the imagery procedure used here, therapist empathy had minimal influence on therapy outcome. Neither the inclusion or elimination of therapist behaviors rated as empathetic had a reliable effect on outcome beyond that produced by the imagery procedure.

Using the EIP as a standard of comparison, the MIP group performance indicated that empathy is not a necessary condition for avoidance behavior reduction, whereas the ECP group performance indicated that empathy is not a sufficient condition for the same outcome. These findings are consistent with the interpretations that relationship factors are relatively unimportant in behavioral procedures and that instructed attention shifts toward and away from symptom-related stimuli are important.

Frequent Citations in the *Journal of Consulting and Clinical Psychology* During the 1970s

W. Miles Cox
Indiana University

Authors who have been cited most frequently in the *Journal of Consulting and Clinical Psychology* during the first half-decade of the 1970s are identified. In turn, these authors' publications that have been cited most frequently are indicated. Most prominent are the work of Julian B. Rotter on the locus of control of reinforcement and Truax and Carkhuff's contributions to training and practice in counseling and psychotherapy.

In their recent survey, Koulack and Keselman (1975) found that the *Journal of Consulting and Clinical Psychology* is one of the most prestigious periodicals among clinical psychologists in terms of where they wish to publish and where they expect important psychological material to be found. To determine the influence of certain contributors on publications in the *Journal*, I identified the most frequently cited authors and their most frequently cited publications during the first 5 years of the present decade.

A frequency distribution was constructed to determine the number of times that any given author was cited among the 12,893 reference entries in the 887 articles appearing in Volumes 34-42 (1970-1974). Each author was assigned 1 point for each entry in the reference section of each article in which his or her name appeared. Next, a frequency distribution was constructed to determine the number of references to each publication by the authors who were cited most frequently.

The names of authors who were cited most frequently are shown in Table 1, and their particular publications that were cited most frequently are indicated in Table 2. It should be recognized that frequency of citation might, of course, be a reflection of factors other than an author's influence per se (cf. Cox, 1977). It is noteworthy in this regard that the work of B. J. Winer heads the list of most frequently cited publications as a result of the widespread use of his statistics book (Winer, 1962) rather than his direct contribution to clinical psychology. Nevertheless, from Tables 1 and 2, we can judge what the prominent areas of clinical research have been during the present

Predicting Violent Behavior from WAIS Characteristics: A Replication Failure

Lois Shawver and Charles Jew
California Medical Facility, Vacaville, California

Kunce, Ryan, and Eckelman have reported some promising evidence on an index for predicting violent behavior derived from differential Wechsler Adult Intelligence Scale (WAIS) characteristics. The present study is an attempt to replicate their findings. Results of this study were unsuccessful.

Many researchers have tried to use psychological tests to detect people prone to commit violence, but their efforts have generally been disappointing. After reviewing recent negative findings, Kunce, Ryan, and Eckelman (1976) described how they analyzed Wechsler Adult Intelligence Scale (WAIS) profiles of a sample of violent and nonviolent male offenders and factored out new predictors of violent behavior. Their most promising index was the ratio of the subject's Similarity score to the sum of his WAIS subtests $\times 100$. A low Similarities ratio score occurred significantly more often in the violent group in both their original and cross-validation samples. However, since identifying a patient as violent could in itself have devastating consequences, it is imperative that any such findings be thoroughly verified before clinicians put them to use. This should be especially true in small cross-validation samples.

Kahn (1959) advanced a hypothesis similar to the one advanced by Kunce et al. Kahn reasoned, as did Kunce et al., that extreme violence is the result of impulsivity due to poor abstract reasoning ability and should be reflected in lower Similarities scores. Kahn's data were based on Wechsler-Bellevue scores of individuals hospitalized for evaluation of legal insanity. Although Kahn found some elements in the test data supporting his impulsivity hypothesis, his Similarity subtest findings were not as predicted. In contrast to Kunce et al., Kahn found that violent offenders did not have a distinctively lower score on the Similarities subtest.

The present study was an attempt to replicate

the Kunce et al. (1976) findings. Their sample "consisted of white males recently court committed as criminally insane or undergoing pretrial mental examination following arrest for a felony" (p. 42). The sample used here was similar. All subjects were white males diagnosed as psychotic. Subjects were not included when a review of court transcripts left doubt as to whether the crime should be judged as violent or nonviolent.

Kunce et al. reported that violent subjects earned lower Similarities ratio scores ($M = 5.14$) than nonviolent subjects ($M = 9.42$) in a cross-validation sample consisting of 7 violent and 7 nonviolent cases. The present study included 16 subjects in the violent sample and 10 in the nonviolent sample. In the present study, the findings of Kunce and his colleagues were not replicated. Not only were the results not significant, but the direction of the findings were reversed as were the findings reported by Kahn. In this study violent subjects earned higher Similarities ratio scores ($M = 10.25$) than did nonviolent subjects ($M = 9.62$).

The conclusion here is that the Similarities ratio score advanced by Kunce et al. has not yet been sufficiently validated to be used by clinicians to predict violent behavior in specific cases.

ESTABLISHING AND MAINTAINING A PROFESSIONAL PRACTICE

MAY 5, 6, 7, 1978

Assessing readiness for a successful private practice; pre-planning, referrals, budgets, fees, taxes.

A CERTIFICATE OF ATTENDANCE WILL BE ISSUED TO PARTICIPANTS

Registration Form

The National Academy of Professional Psychologists
15 Columbus Circle, New York, N.Y. 10023

Seminars held at the Sheraton Ocean Inn, Palm Beach, Florida,

JCC 2

I would like to attend Seminar(s) _____

Name _____ Highest Degree _____

Home Address _____

City _____ State _____ Zip Code _____

☐ Deposit check enclosed ☐ Payment in full enclosed

\$300 Registration includes tuition and course materials. \$50 Deposit check must accompany registration. Deposit will be refunded if cancelled at least 2 weeks prior to seminar date. Hotel reservations are to be made directly by the participant. Hotel reservations without deposit will be taken on a space available basis only.

These are limited attendance workshops. Make reservations early.

ANNOUNCING!

The Addison-Wesley Series in Clinical and Professional Psychology

edited by Leonard D. Goodstein, *Arizona State University*

To keep you up-to-date, Addison-Wesley offers ten paperback introductions that survey and organize the latest research developments in major sub-areas of clinical psychology. Each is written by an expert or experts in the field and is the ideal middle ground between out-of-date, encyclopedic texts and sketchy journal articles. Whether taken as a whole for introductory level courses or singly for seminars or individual study, this adaptable series can help both students and practitioners learn about and keep in touch with the current state of the field.

Seven titles are being published in 1978:

A Biofeedback Primer

Edward B. Blanchard (SUNY, Albany) and
Leonard H. Epstein (University of Tennessee)
00338, 228 pp, Jan. 1978

Psychotherapy & Process: The Fundamentals of an Existential-Humanistic Approach

James F. T. Bugental (Private Practice, San
Rafael, California; Home Faculty, Humanistic
Psychology Institute) 00333, 192 pp, Feb. 1978

A Primer On Sleep And Dreams

Rosalind Dymond Cartwright (University of
Illinois, Chicago Circle) 00941, 176 pp, Jan. 1978

Psychoanalytic Psychotherapy

edited by George D. Goldman and
Donald S. Milman (Adelphi University)
02513, 192 pp, Jan. 1978

Consulting With Human Service Systems

Leonard D. Goodstein (Arizona State Univer-
sity) 02397, 192 pp, Jan. 1978

Behavior Therapy: A Clinical Introduction

Richard I. Lanyon and Barbara P. Lanyon
(Arizona State University) 04100, 192 pp,
Feb. 1978

Minority Health Issues In Mental Health

William D. Smith, Ann K. Burlew, Myrtis H.
Mosley, and W. Monty Whitney (University of
Cincinnati) 07478, 192 pp, June 1978

Community Psychology

Christopher B. Keys (University of Illinois,
Chicago Circle)

Sex Role Issues In Mental Health

Stephanie A. Shields (University of California
at Davis)

10 Day Free Examination!

Please send me on 10-day examination the books I have checked below. I understand that I may return any of them in ten days and the invoice will be cancelled. Also please send me information on future books in this series as they are published.

CLINICAL QUANTITATIVE METHODS

By RICHARD W. J. NEUFELD, Ph.D.

CONTENTS: Group Versus Single-Subject Approaches to Obtaining Clinically Relevant Information. Personal Questionnaire Techniques. Statistical Inference in the Single Case. Quantifying Patterns of Symptom Change. Stochastic Process Analysis. Some Methods Facilitating Decision-Making in Clinical Practice. Clinical Use of the Theory of Signal Detectability. Multiple Regression and Discriminant Function Analysis. Canonical Correlation. Introduction to Empirical Classification Approaches. Appendix A: Basic Vector Calculations. Appendix B: Basic Matrix Calculations. Appendix C: Iterative Computation of Latent Roots and Latent Vectors.

1977, 208 pp., 19 illus., \$14.50/£10.30

ISBN: 0-8089-1035-3

THE HUMAN DIMENSION IN PSYCHOANALYTIC PRACTICE

Edited by KENNETH A. FRANK, Ph.D.

CONTENTS: K. A. Frank, Introduction. H. F. Searles, The Development of Mature Hope in the Patient-Therapist Relationship. H. A. Rosenfeld, Personal Experiences in Treating Psychotic Patients. H. Guntrip, My Experience of Analysis with Fairbairn and Winnicott (How Complete A Result Does Psychoanalytic Therapy Achieve?). H. Kelman, My Philosophy of Psychotherapy. H. Bruch, The Tyranny of Fear. R. R. Greenson, That "Impossible" Profession. M. M. R. Khan, From Secretiveness to Shared Living. D. Shainberg, Transforming Transitions in Patients and Therapists. P. Olsen, Recognitions of the Soul. S. Basescu, Anxieties in the Analyst, An Autobiographical Account. A. Ben-Avi, On Becoming an Analyst. E. Singer, The Fiction of Analytic Anonymity.

1977, 224 pp., \$14.75/£10.50 ISBN: 0-8089-1039-6

Send payment with order and save postage plus 50¢ handling charge. Orders under \$15.00 must be accompanied by payment.

Prices are subject to change without notice.

U.S. customers please note: On prepaid orders—payment will be refunded for titles on which shipment is not possible within 120 days.

CHARLES C THOMAS • PUBLISHER

BEHAVIOR THERAPY IN CLINICAL PRACTICE: Decision Making, Procedure and Outcome by Ernest G. Poser, *McGill Univ., Montreal, Quebec, Canada*. Foreword by H. J. Eysenck. Practical applications of social conditioning principles are presented in this text. Divided into four sections, the text explores specific fears, physical expressions of social withdrawal, socially disapproved behavior, and current problems in behavior modification. '77, 204 pp., 4 il., 1 table, \$13.50

MUSIC THERAPY: An Introduction to Therapy and Special Education Through Music (2nd Ptg.) by Donald E. Michel, *Texas Woman's Univ., Denton*. Without extensive use of technical language, this text presents a rationale for the use of music therapy in a wide variety of medical/psychological situations. The history of music therapy; its basic theoretical rationales; and its applications in therapy, rehabilitation, and special education are also discussed. '77, 152 pp., 2 il., \$9.75

DEVELOPMENT AND DISORDERS OF SPEECH IN CHILDHOOD (4th Ptg.) by Isaac W. Karlin; David B. Karlin, *Mount Sinai Hospital, New York City*; and Louise Gurren, *New York Univ., New York City*. In this book the authors describe the normal course and development of speech and language from its origin in infancy through its maturation during adolescence. The anatomical, physiological and psychological aspects of the speech mechanism are presented. The causes of both organic and functional (including emotional) speech and language disorders are also explained. '77, 324 pp., 63 il., 10 tables, \$12.75

THE AMERICAN ALCOHOLIC: The Nature-Nurture Controversy in Alcoholic Research and Therapy (2nd Ptg.) by William Madsen, *Univ. of California, Santa Barbara*. This is a forthright text which calls into question many of the accepted ideas about alcoholism, and it will provide provocative reading for anyone involved in the field. *The Journal of Alcoholism* gave this book a most enthusiastic review: "It was a pleasure to read this thoughtful and scholarly exposition, with its well marshalled facts, and considered opinions, which provide much food for thought and issue many challenges." '77, 272 pp., 4 il., \$11.50

REFLEX EPILEPSY, BEHAVIORAL THERAPY AND CONDITIONAL REFLEXES by Francis M. Forster, *Univ. of Wisconsin, Madison*. The first portion of this singularly comprehensive text deals with the various causes of the condition including visual and auditory stimuli; higher cognitive functions, somatosensory stimulation; and eating and movement. The latter half of the book considers such topics as classification and differential diagnosis, and the methods, principles of application, and role of medication in treatment. '77, 328 pp., 87 il., 22 tables, \$22.75

INDIVIDUALIZED LEARNING PROGRAM FOR THE PROFOUNDLY RETARDED by M. Susan De Vore, *Peoria, Illinois*. This book combines a series of lesson plans with an easy method of collecting data and recording the progress attained by the child. The lesson plans are divided into six sections that individually cover programs for teaching self-care, socialization, communication, cognitive function, gross motor skills and fine motor skills. '77, 256 pp. (9 3/4 x 6 3/4), 35 il., \$11.00, spiral (vinyl)

BASIC APPROACHES TO GROUP PSYCHOTHERAPY AND GROUP COUNSELING (2nd Ed., 2nd Ptg.) edited by George M. Gazda, *Univ. of Georgia, Athens*. (20 Contributors) Experts in the field summarize such techniques as psychodrama, psychoanalysis, existential group psychotherapy, reality therapy, transactional analysis, rational-emotive therapy, conjoint family therapy and gestalt therapy. Group counseling is discussed with respect to the eclectic, behavioral and teleoanalytic positions. '77, 560 pp., 9 il., \$16.75

CLINICAL USE OF PSYCHOTHERAPEUTIC DRUGS (5th Ptg.) by Leo E. Hollister, *Stanford Univ. School of Medicine, Palo Alto, California*. Drugs used in treating emotional disorders of children and adults are covered. Each class of drugs is considered in relation to the chemical and pharmacological differences among its members, pharmacological properties and pharmacokinetics as these relate to their clinical use, specific clinical indications, general principles of use, use in combination with other drugs, side effects, and toxicology. '77, 200 pp., 11 il., 13 tables, \$8.95

Behavioral Instruction: An Evaluative Review

1977 200 pages \$5.00

Provides a comprehensive overview and evaluation of behavioral instruction. Included are sections on the history and development of behavioral instruction; a detailed look at Keller's Personalized System of Instruction, its empirical and theoretical basis and basic principles; other behavioral systems of instruction; management and grading in behavioral instruction courses; comparisons of behavioral and conventional instruction; an extensive component analysis of behavioral instruction; and a discussion of present extensions and future directions of behavioral instruction.

To order this book, please send full payment or institutional purchase order to:

Keller's Personalized System of Instruction: An Appraisal

Bruce A. Ryan, author; *Foreword* by Fred S. Keller. Offers the reader an objective assessment of the relevance of behavior theory, the role of unit tests, the appropriateness of the student proctor, and the success of self-evaluation in this increasingly popular approach to college-level education. In addition to an analytical review of the current literature, future directions for PSI are proposed and an invaluable "how-to" bibliography is included. 1974. 32 pp. \$2.

Graduate Study in Psychology for 1978-1979

An indispensable
resource book for
prospective
graduate students
and for college
counselors

Graduate Study in Psychology for 1978-1979

This book provides specific information on 500 graduate programs in the United States and Canada: their application procedures, admission requirements, degree requirements, tuition, financial assistance, internships and minority considerations.

It also furnishes general information on how to apply to graduate school and for the first time includes a section of statistical data relevant to trends in graduate training.

600 pages. \$6.

EIDETICS

a visual system for individual and group psychotherapy by AHSEN

The eidetic image is a bright and lively inner mental picture which elicits a vast spectrum of psychological information. Seen like a movie image, the eidetic causes the person to experience his emotional states with vivid sensations and positive transformation of behavior and consciousness. A normal and fascinating image phenomenon, the eidetic exists in both adults and children, but stays dormant unless helped to become activated through special techniques. Ahseen's acclaimed work on Eidetic Technique, Research, and Therapy Procedures has opened a unique and exciting approach to mind.

SOME VIEWS ON AHSEN'S WORK

- "Unmatched in the clinical literature . . . a methodological advance."
— *The American Journal of Psychiatry*
- "Compared to Akhter Ahseen's penetrating analysis of imagery formation and eidetic processes, all other clinical uses of imagery appear singularly embryonic."
— Arnold A. Lazarus, Ph.D.
- "It is possible that what Ahseen has achieved is a new means of communication, more subtle than verbalization of facts and associative thinking."
— *Behavior Therapy*
- "Adds to currently accepted principles of developmental psychology as exemplified in psychoanalysis and Piaget's work."
— *Pakistan Journal of Psychology*
- "One of the most significant developments yet to emerge in psychotherapy since Freud's psychoanalysis."
— *The Glasgow Journal of Psychology*
- "An exciting and ingenious way of getting at conflict areas."
— *Contemporary Psychology*
- "Really a break-through . . . Its extreme usefulness for divergent schools . . . cannot be denied."
— *Manab Mon, Behaviour and Behaviour Control*
- "Of great value . . . a rapid approach to resolving the patient's problems."
— *Indian Journal of Psychiatry*
- "A very original and very promising approach."
— *Zeitschrift für Psychologie*
- "American Psychiatry is indeed fortunate to have the stimulation and enrichment of Ahseen's highly original and creative presence."
— *Existential Psychiatry*
- "Akhter Ahseen has written an original work which does full credit to Isadore Chien's thesis that philosophy and science can and should be amalgamated to create a systematic view of reality. For that part of the psychological reality with which he deals, Ahseen has given a theoretical framework and a methodology which is one example of how one can unite a metaphysical position with a physical system and put the Cartesian dichotomy aright."
— *International Journal of Clinical and Experimental Hypnosis*

JOURNAL OF
CONSULTING
AND
CLINICAL
PSYCHOLOGY

AMERICAN PSYCHOLOGICAL ASSOCIATION

ISSN 0022-006X

The *Journal of Consulting and Clinical Psychology* publishes original contributions on the following topics: (a) the development, validity, and use of techniques of diagnosis and treatment in disordered behavior; (b) studies of populations of clinical interest, such as hospital, prison, rehabilitation, geriatric, and similar samples; (c) cross-cultural and demographic studies of interest for the behavior disorders; (d) studies of personality and of its assessment and development where these have a clear bearing on problems of consulting and clinical psychology; or (e) case studies pertinent to the preceding topics. In order to improve the use of journal resources it has been agreed by the two Editors concerned that the *Journal of Consulting and Clinical Psychology* will no longer consider manuscripts dealing with the etiology or descriptive pathology of abnormal behavior, and the *Journal of Abnormal Psychology* will no longer consider articles dealing with the diagnosis or treatment of abnormal behavior. Articles that appear to have a significant contribution to both of these broad areas may be sent to either journal for editorial decision. Papers of a theoretical nature will also be considered within the space limitations of the journal.

Manuscripts: Submit manuscripts in triplicate to the Editor-elect, Sol L. Garfield, Department of Psychology, Washington University, St. Louis, Missouri 63130 according to instructions provided elsewhere in the journal. Authors submitting a manuscript previously considered for publication in another APA journal are invited to inform the Editor, who will then seek to obtain independent reviews, thus avoiding the possibility of repeated reviewing by the same consultant.

Copyright and Permissions: All rights reserved. Written permission must be obtained from the American Psychological Association for copying or reprinting text of more than 500 words, tables, or figures. Permissions are normally granted contingent upon like permission of the author, inclusion of the APA copyright notice on the first page of reproduced material, and payment of a fee of \$10 per page, table, or figure of APA material. Permission fees are waived for authors who wish to reproduce their own article. Address requests for permission to the Permissions Office, American Psychological Association, 1200 Seventeenth Street, N.W., Washington, D.C. 20036.

Subscriptions: Subscriptions are available on a calendar year basis only (January through December). Nonmember rates for 1978: \$32 domestic, \$34 foreign, \$6 single issue. APA member rate: \$16. Write to Subscription Section, APA.

Reprints: Authors may order reprints of their articles from the printer when they receive proofs.

Back Issues and Back Volumes: For information regarding back issues or back volumes write to Order Department, APA.

Microform Editions: For information regarding microform editions write to any of the following: Johnson Associates, Inc., P.O. Box 1017, Greenwich, Connecticut 06830; University Microfilms, Ann Arbor, Michigan 48106; or Princeton Microfilms, Princeton, New Jersey 08540.

Change of Address: Send change of address notice and a recent mailing label to the attention of the Subscription Section, APA, 30 days prior to the actual change of address. APA will not replace undelivered copies resulting from address changes; journals will be forwarded only if subscribers notify the local post office in writing that they will guarantee second-class forwarding postage.

Published bimonthly (beginning in February) in one volume per year by the American Psychological Association, Inc., 1200 Seventeenth Street, N.W., Washington, D.C. 20036. Printed in the U.S.A. Second-class postage paid at Washington, D.C., and at additional mailing offices.

An Outcome Study of Short-Term Communication Training with Married Couples

Norman Epstein and Elizabeth Jackson
State University of New York at Buffalo

Communication training, interaction insight training, and no treatment were compared for changes in marital verbal interaction and spouses' ratings of each other on the Barrett-Lennard Relationship Inventory. Fifteen couples were randomly assigned to the three groups. Both treatments involved five 1½-hour group sessions over 3 weeks, led by the same male and female cotrainers. During assessments, discussions of individual couples were tape recorded and coded. The pretest-posttest interval for waiting list controls was equal to that for the treatment groups. Communication training produced a significant increase in assertive requests, compared to insight treatment and no treatment. Both treatments reduced disagreement significantly. Communication training produced a greater decrease in attacks and a greater increase in spouse-rated empathy than the control condition, but insight training and no treatment did not differ on these variables. Generally, communication training led to more extensive changes in spouses' verbal behavior and perceptions of marital communication than insight training. Further research is suggested to test the limits of this intervention for modifying various classes of maladaptive marital interaction.

In recent years, treatments of marital discord frequently have been designed to foster clear communication between intimates, with the expectation that such behavioral changes would be associated with increased marital satisfaction (e.g., Bolte, 1970; Ely, Guernsey, & Stover, 1973; Lederer & Jackson, 1968; Wells, Figurel, & McNamee, 1975). Raush, Barry, Hertel, and Swain (1974) noted that conflict is inevitable when partners in a close relationship seek to satisfy their varied needs, and they argue that clear communication is a prerequisite for conflict resolution. Although poor communication may be a consequence of marital conflict, the lack of information exchange may itself impede resolution of differences and interpersonal tensions (Bardill, 1966; Raush et al., 1974). It is likely that

poor communication and marital dissatisfaction mutually reinforce each other.

Empirical investigations of the relationship between communication clarity and marital satisfaction provide evidence that their association is quite strong. Relying on self-report measures, Navran (1967) and Murphy and Mendelson (1973) found high positive correlations between spouses' scores on marital satisfaction inventories and their scores on questionnaires assessing openness of marital communication. In Raush et al.'s (1974) study, spouses' use of rejection and coercion, coded from actual interactions, was significantly related to poor resolution of conflict. Relationships characterized by avoidance had a static quality in which little problem solving took place. Epstein and Jackson (Note 1) examined the relationships between spouses' ratings of empathy, congruence, and unconditional positive regard received from each other and categories of their verbal interaction coded from tapes by independent raters. Perceived empathy was related inversely to frequencies of self-justification and disagreement

by the spouse and related positively to the spouse's use of statements that revealed feelings, offered support, or conveyed agreement. Ratings of the spouse's congruence were related inversely to the frequency of self-justification. These findings suggest that patterns of clear, supportive communication are associated with components of marital satisfaction.

Two basic patterns of unclear communication commonly observed in disturbed marriages are avoidance and active escalation of conflict. Olson (1972) and Raush et al. (1974) suggested that spouses who feel threatened by potential confrontation on relationship issues often withdraw from direct communication. They rely on evasive messages such as denials, self-justification, and disqualification¹ rather than stating their opinions and feelings clearly. On the other hand, conflicts may be escalated directly through issue expansion (e.g., "You always _____"), disparagement, and other personal attacks (Raush et al., 1974). Both avoidance and escalation of attack decrease the exchange of information necessary for constructive problem solving.

Avoidance and attack closely parallel the two modes of behavior described by Alberti and Emmons (1974) as characteristic of people who have deficits in assertive behavior: nonassertion (withdrawal) and aggression. They outline procedures designed to improve an individual's communication skills by substituting specific assertive messages for evasive and/or attacking messages. Although group assertiveness training has been shown to increase clarity and directness of subjects' communication in role playing situations, Alberti and Emmons question whether the newly learned behaviors will generalize to interactions with significant others outside the training group. Studies by Eisler and Hersen (1973) and Lehman-Olson (1976) provide some encouraging evidence for the effectiveness of assertiveness training with individuals, focusing on their marital relationships. However, both Alberti and Emmons and Lehman-Olson suggested that assertiveness training with married persons would be more effective if spouses participated together. The present study draws on tech-

niques of assertion training for in vivo modification of unclear communication between spouses.

In the present study, a group treatment designed to increase clarity and assertiveness of communication by means of active practice (e.g., role playing) was administered to couples who complained of difficulties in communicating. Its effects on both verbal behavior and spouses' self-reported perceptions of each other's empathy, congruence, and positive regard were compared to those found with an alternate treatment focusing on insight into behavioral interaction patterns and with a no-treatment control group. The "interaction insight" treatment fostered spouses' understanding of repetitive maladaptive behavioral patterns (e.g., interruptions) in their relationship, without the repeated practice of assertive messages incorporated in the communication treatment. Inclusion of this alternate treatment group allowed a test of the hypothesis that active practice of more effective communication patterns will produce not only more assertive behaviors but also a greater increase in spouse-perceived openness of communication than that resulting from insight training alone.

The specific hypotheses were that in a pretest-posttest design, (a) subjects who received communication training would exhibit a greater increase in specific assertive messages than subjects in the interaction insight and no-treatment control groups; (b) subjects receiving communication training would exhibit a greater decrease in nonassertive messages (e.g., disqualification, self-justification) and aggressive messages (e.g., attack) than subjects in the other groups; (c) subjects who received communication training would report greater increases in their spouses' congruence (open, direct communication) than subjects in the other groups;

¹ A disqualification is a message that invalidates another message sent previously or concurrently. Disqualifying one's own message allows one to express an idea or feeling but not take responsibility for it. Disqualifying another person's message communicates that one does not acknowledge the validity or even the existence of the other's ideas and feelings (Olson, 1972; Watzlawick, Beavin, & Jackson, 1967).

(d) subjects in both the communication and interaction insight groups would report increases in empathy and positive regard received from their spouses, with the former treatment producing greater increases on these dimensions; and (e) improved conflict resolution, evidenced by fewer disagreements, would result from both treatments, with communication training producing the stronger effect.

Method

Subjects

Couples who responded to public media announcements of a research project involving free workshops for "marital communication problems" initially were screened by phone in order to select subjects who were married at least 2 years, had completed high school, were not presently in counseling, were not judged to be in psychological crisis, and did not exhibit severe psychopathology. These criteria were used to insure a moderate degree of homogeneity in the sample. Appropriate referrals were made for callers who did not meet the above criteria.

A pretreatment interview with each couple served as a second screening. Three interviewed couples were referred for more extensive marital therapy based on the experimenters' judgments that their problems were more severe than a communication disorder. The remaining 16 couples who were judged appropriate for the workshops then were randomly assigned to the communication training group (6 couples), the interaction insight group (5 couples), and the no-treatment "waiting list" group (5 couples). During the course of treatment, 1 couple dropped out of the insight group. Subjects placed on the waiting list received treatment at the conclusion of the study.

Materials and Procedure

During pretreatment and posttreatment assessments for individual couples, each subject completed the Barrett-Lennard Relationship Inventory (Barrett-Lennard, 1962), indicating the degree of empathy, congruence, and unconditional positive regard generally received from the spouse. This scale has been used in previous studies (e.g., Quick & Jacob, 1973; Wells, Figurel, & McNamee, 1975) to assess marital satisfaction.

Next, the couple was instructed to discuss their communication problems for 15 minutes with a male and a female interviewer present. The interviewers did not intervene in the couple's discussion after giving the following instructions:

In order for us to get an idea about how the two of you talk with each other, we would like

to spend 15 minutes giving each of you an opportunity to talk about what communication is like between you. What seems to happen when you want to talk to each other about important matters? If there is a problem with your communication process, what is it, and what seems to be its source? Please direct your comments to each other, not to us, and we will listen.

Following this warm-up period, the couple was asked to continue discussing their communication pattern for 10 minutes without the interviewers present. Interviews were tape recorded with each couple's written permission.

Subjects in the two treatment groups met for five 1½-hour sessions over a 3-week period. Both groups were led by the same male and female cotrainers, who were experienced in both modes of treatment and were unaware of the experimental hypotheses. Although the treatment formats were different for the two groups, the major topic discussed at each session (e.g., expression of caring, cooperation, problem solving) was the same. During each session, subjects in both treatments formed smaller groups of two or three couples to perform specific exercises. At the beginning and end of each session, the total group membership met to discuss common communication issues.

The communication treatment emphasized the practice of specific assertive requests, opinions, and statements of feeling. During the first session, couples were presented a set of guidelines for clear communication. Alberti and Emmons' (1974) arguments regarding "assertive rights" in interpersonal relationships were discussed. All sessions included modeling of assertive communication by cotrainers, practice by each couple with issues they chose from their own relationships, and behavioral feedback to each subject from the trainers and other group members. Instances of unclear and nonassertive communication were pointed out, and alternate ways of expressing the intended message were presented for the individual to role play. Couples increasingly coached each other on expressing messages precisely and directly. The cotrainers intervened actively and reiterated the communications guidelines frequently.

The insight treatment focused on the particular interaction patterns of each couple that confused or frustrated the spouses. The cotrainers instructed subjects in the observation of verbal and nonverbal messages that exacerbate conflict. A major goal was to increase each subject's awareness of the impact his/her behavior had on the spouse's feelings and behavior. Each couple received extensive feedback regarding interaction patterns from the cotrainers and other couples. Delineation and practice of alternate modes of clear communication was minimal.

Each couple's posttest interview was held within a week of the last treatment session and was identical in procedure to the pretest. The pretest-posttest interval for the control group was equal to that for the treatment groups. All couples were given an opportunity for further treatment.

Results

Eleven categories of each subject's taped verbal behavior were scored by two independent coders from a 5-minute segment of each couple's discussion while alone. Based on an a priori decision to allow a short time for each couple to adjust to the interviewers' departure, the coded segment always was the 3rd through the 7th minute of discussion. The coding categories and their respective interrater reliabilities, calculated as phi coefficients (Herbert, Note 2), were assertive request, 1.00; self-revelation, .85; specific statement, .86; general statement, .83; asking for feedback, 1.00; disqualification, .90; agreement, .98; disagreement, .80; support, 1.00; attack, .84; and self-justification, .84.

Pretest, posttest, and change (posttest minus pretest) scores were computed for each subject on the proportion of total speech acts coded into each of the 11 verbal behavior categories and ratings of spouse's empathy, congruence, and positive regard. Since spouses were assessed as couples, their scores on each dependent measure were not considered to be independent, and the analyses were conducted with couples' scores computed as the mean score for each husband and wife. Therefore, the *ns* for analyses were 6, 4, and 5 couples in the communication, insight, and control groups, respectively.

Analyses of variance for pretest scores indicated no significant initial differences among the three groups on the dependent variables. The fact that only 1 of the 14 pretest *F* values reached the level of $p = .10$, which would be expected by chance alone, and only 2 reached $p < .20$, served as evidence that the random assignment of couples to groups produced adequate matching.

Further one-way analyses of variance and planned (one-tailed) *t* tests were used to compare change scores for the groups. The potential problem of highly correlated dependent measures, which would result in redundant tests in the major analyses, was assessed by computing the intercorrelations of all the dependent variables. The mean absolute value of these 91 correlations, calculated with z_r transformations (Edwards, 1976), was .22 (*ns*) and represents a mean

of less than 5% shared variance. Although 3 of the 7 correlations exceeding .40 (16% overlap) were those among the three Relationship Inventory subscales, the important conceptual distinctions inherent in the subscales and the differential predictions made for them in this study were considered to be sufficient grounds for analyzing them separately.

Of the one-way analyses of variance for the three subject groups, the strongest effects were found for the following dependent variables: assertive request, $F(2, 12) = 27.65$, $p < .001$; disagreement, $F(2, 12) = 3.42$, $p = .067$; attack, $F(2, 12) = 2.08$, $p = .168$; spouse-rated empathy, $F(2, 12) = 1.75$, $p = .215$; asking for feedback, $F(2, 12) = 1.69$, $p = .225$; and self-justification, $F(2, 12) = 1.37$, $p = .290$. No other variable produced an *F* value exceeding 1.00.

Planned *t* tests indicated a significant increase in assertive requests for the communication group, relative to the insight group, $t(12) = 6.51$, $p < .001$, and relative to the control group, $t(12) = 6.03$, $p < .001$. Change in assertive requests did not differ for the insight and control groups, $t(12) = -.82$. Significantly greater reduction in percentage of disagreements was found for the communication group, $t(12) = -1.84$, $p < .05$, and the insight group, $t(12) = -2.52$, $p < .05$, relative to the control group. Contrary to the hypothesis, the decrease in disagreement was not significantly different for the insight and communication groups, $t(12) = .89$.

As predicted, communication training produced a significantly greater decrease in attacks than the no-treatment control, $t(12) = -2.03$, $p < .05$. Insight training produced an intermediate decrease in attacks that did not differ significantly from the other groups. There were nonsignificant trends toward decrease in use of self-justification in the communication group, relative to the control group, $t(12) = -1.41$, $p < .10$, and in the insight group, relative to the control group, $t(12) = -1.46$, $p < .10$. Similarly, there were nonsignificant trends toward an increase in asking for feedback in the communication group, relative to the control group, $t(12) = 1.42$, $p < .10$, and in the insight group, rela-

tive to the control group, $t(12) = 1.72$, $p < .10$. No other significant differences were found among the three groups for the remaining verbal coding categories.

Analyses of subjects' change scores on the Relationship Inventory indicated a significant increase in spouse-perceived empathy in the communication group, relative to the control group, $t(12) = 1.79$, $p < .05$. The trend toward greater increase in empathy for the communication group than for the insight group was not significant, $t(12) = 1.25$. The trend toward greatest increase in spouse-rated congruence in the communication group also was not significant.

Table 1 presents the pretest, posttest, and change-score group means for the significant effects.

Discussion

The significant decrease in disagreements of subjects in the two treatment groups suggests that they were moderately successful in reducing overt conflict in this sample of married couples. Although communication training did not produce a greater decrease in overt disagreement than interaction insight

training, the communication training was more effective in reducing attack behaviors. The somewhat smaller decrease in statements of disagreement in the communication group might be due to the fact that the assertiveness training encouraged direct expression of feelings and opinions, including disagreement. An unanswered question is whether or not training in the assertive expression of disagreement along with decreased attacking will lead to greater conflict resolution than insight training in the long run.

The significant increases in assertive requests and spouse-perceived empathy in the communication group indicate that a short-term structured intervention involving both partners can have a measurable impact on both overt interactions and spouses' experiences of each other's communication. The overall findings provide evidence that communication training produces greater changes in some categories of subjects' behavior than interaction insight training. The lack of significant change in other categories of verbal behavior (e.g., disqualifications, self-revelation) and in spouse-perceived congruence and unconditional positive regard suggests that the effectiveness of this communication training for couples should be tested further. It is important to determine whether treatment of longer duration would produce comparable change across the various communication categories or whether certain classes of behavior are particularly resistant to change with this intervention. Since the impact of communication training on spouses' perceptions of change was less extensive, it appears that it may be easier to implement behavioral changes than attitudinal changes in close interpersonal relationships. A question for future research is whether spouses' perceptions of behavioral change will follow in time.

Rating Scales for the Identification and Treatment of Hyperkinesis

Patricia Goldring Zukow, Arnold H. Zukow, and P. M. Bentler
University of California, Los Angeles

In response to the need for a simple instrument to aid the psychologist, educator, or physician in the identification and treatment of hyperkinesis, parent and teacher rating scales were developed. Multivariate analysis of the parent ratings of clinical and control subjects indicated three factors: Factor 1, Excitability; Factor 2, Motor Coordination; and Factor 3, Directed Attention. A factor analysis of the teacher form yielded two similar factors, Attention/Excitability and Motor Coordination. Analysis of variance of each factor score revealed highly significant differences between clinical and control subjects. Cutoff scores were developed to aid in diagnostic decision making. These scores correctly identified a large percentage of clinical and control subjects.

Many concerned professionals have expressed well-founded reservations about the use of medication (Cantwell, 1975; Fish, 1975; Myers & Pless, 1976; Rie, 1975; Rie, Rie, Stewart, & Ambuel, 1976; Sroufe & Stewart, 1973; Grossman, Note 1) and the effectiveness of various therapeutic approaches (Gittelman-Klein et al., 1976; Keogh & Margolis, 1976) in the management of hyperactive children. Several complete reviews and analyses of both the positive effects as well as the drawbacks of drug therapy have recently appeared (Rie et al., 1976; Whalen & Henker, 1976). In spite of the fortunate fact that medication can yield behavioral improvement in a large proportion of cases of hyperkinesis (Conners, 1972; Conners, Rothschild, Eisenberg, Schwartz, & Robinson, 1969; Conners, Taylor, Meo, Kurtz, & Fournier, 1972; Sleator & von Neumann, 1974) or that behavior modification techniques affect short-term or situational improvement in academic performance (Gittelman-Klein et al., 1976; O'Leary, Pelham, Rosenbaum, & Price,

1976; Varni, 1976), the specific biological and behavioral bases and diagnostic criteria for hyperkinesis remain uncertain. There is common agreement that hyperkinesis contains elements of high activity level associated with learning and behavioral disorders (Laufer & Denhoff, 1957; Millichap, 1968; Stewart, Pitts, Craig, & Dieruf, 1966; Werry, 1968), but the practical issue of identification remains unresolved (Rie, 1975; Grossman, Note 1).

Many physical and behavioral disorders can be reliably classified on the basis of first-hand observations by a single professional. However, the identification of hyperkinesis must involve the active cooperation of both parents and teachers. One study reported, for example, that only 10 of 46 subjects could have been correctly identified on the basis of a single examination conducted by one individual (Sleator & von Neumann, 1974). As Rie (1975) has noted, satisfactory assessment of a child's behavior must be based on evaluations by several persons well acquainted with many facets of the child's everyday life. It follows that the correctness of classification, consequent assignment of treatment condition or therapy, and assessment of behavioral changes will depend heavily on the adequacy of behavioral measurement provided by teachers and parents.

This study was supported by U.S. Department of Health, Education, and Welfare National Institute on Drug Abuse Grant DA1070.

Requests for reprints should be sent to Patricia G. Zukow, Department of Psychology, University of California, Los Angeles, California 90024.

Teachers are acquainted with a broad range of children engaged in a great number of school activities and can thus compare children's behavior to standards for their age and community; parents, of course, can provide observations from their daily contact with their own children and others in a variety of naturalistic settings.

There is as yet little consensus regarding the perceived behavioral bases of the hyperkinetic syndrome. Several comprehensive behavior rating scales designed to be used by parents and teachers in evaluating problem behavior succeed in differentiating between hyperkinetic and normal children (Blunden, Spring, & Greenberg, 1974; Conners, 1969, 1970; Kupietz, Bialer, & Winsbert, 1972). However, these instruments do not specify the facets of behavior involved in hyperkinesis. So far, the instruments designed for the specific purpose of identifying hyperkinesis have been inadequately researched (Davids, 1971) or they evaluate behavior too specific in nature to capture the clinical complexity of hyperkinetic syndrome (Werry & Sprague, 1970). Blunden et al. (1974) identified a single hyperactivity factor in their teacher rating data of normal subjects. Aspects of hyperactivity included restlessness, impulsiveness, and low perseverance, in addition to the concepts of distractibility and low concentration. Thus in the Blunden et al. study, the presence of one aspect of hyperactivity implied the presence of the others. Conners (1969), in contrast, has found that distractibility and concentration difficulties, along with poor coordination, represented a daydreaming/inattentiveness factor that was clearly distinct from hyperactivity in teacher rating scales. According to teachers a hyperactive child might, or might not, also be shown to have coordination and concentration problems. Finally, Conners (1970) demonstrated that parents who rated behavioral symptoms clustered their symptoms into several distinct dimensions, but that it was primarily one dimension—aggressive conduct disorder—that proved to differentiate normal versus clinic patients and neurotic versus hyperkinetic children. Although this factor makes sense as an identifier of hyperkinesis

because it includes behaviors such as restlessness and temper, the dimension seems to include irrelevant behaviors such as having problems with peers and siblings and excludes such relevant behaviors as poor coordination and inattentiveness that may lead to problems in school. It is apparent that even though some differential diagnosis is possible with existing instruments, the behavioral basis for the disorder remains uncertain.

A recent study by Langhorne, Loney, Paternite, and Bechtoldt (1976) analyzed certain chart, teacher, parent, and psychiatrist ratings of a variety of variables considered to be relevant to the diagnosis of hyperkinesis. Using factor analysis they found that chart raters and psychiatrists were using the same basis for judgments of hyperactivity. Chart raters and teachers tended to assess excitability, but only teachers agreed regarding information about attention difficulties. Although Langhorne et al. interpreted their results as reflecting source of data rather than intrinsic characteristics of hyperkinesis, it is difficult to evaluate their results. All their analyses were based on only a very small, inadequately rationalized subset of variables, which were also subjected to unnecessary transformation prior to analysis. It is clear that additional studies of this issue are called for.

The current research is addressed to two interrelated goals. First, it aims at clarifying the behavioral bases of hyperkinesis as seen in parent and teacher reports. Second, it aims to provide a measure of hyperkinetic behavior that is relevant to the objective classification and treatment of hyperkinesis and to the assessment of significant behavioral changes.

Parent Form

Method

Initial item pool. Since it seemed possible that hyperkinesis as perceived by the parent might involve several interrelated, but distinct, aspects of behavior, items were written by the second author to cover these areas. The first cluster of items was intended to assess "classical" hyperkinetic behavior, including such behaviors as being quick-tempered and explosive. Items and descriptions found in

other scales and observed in clinical rounds, conferences, and journals were modified and adopted. The second group of items was directed toward assessing motor coordination, such as the ability to button without difficulty. These items were included to clarify the observation that poor coordination seems to accompany daydreaming and inattentive behavior more closely than hyperactivity per se (Conners, 1969). The third type of item was concerned with the inability to sustain continuous participation in, and completion of, structured activities related to learning and school problems, as perceived by the parent. This includes behavior such as daydreaming, which had been found in previous work to be possibly distinct from the first item type but which was clearly implicated in the hyperkinetic syndrome (Conners, 1969). A total of 28 items were written. Instructions required the parent, usually the mother, to "circle the answer that most applies to your child." Possible responses were yes or no, although one item was a three-category item collapsed to yes/no for analysis.¹

Subjects. The questionnaire was administered to mothers of children attending cooperating public elementary schools and private preschools and, after initial screening for hyperkinetic behavior problems, to mothers of a subset of the children referred to a private pediatric practice. At the time of evaluation the children were not receiving medication for hyperkinetic behavior. Mothers of the public school children received the questionnaire from teachers who were selected by the principal or director of the schools. Completed forms were returned to the teachers. The schools were chosen to be representative of the socioeconomic class of the children predominantly in this private practice, that is, skewed slightly toward upper-middle class. Various private physicians, mental health practitioners, school personnel, and concerned nonprofessionals referred children to a private pediatric practice for evaluation of possible hyperkinetic disorder. The judgments of the examining pediatrician, the second author, were based on physical examination, medical and family histories, plus behavioral evidence reported by parents and teachers. Inclusion in the clinical group depended on consistent evidence of behavioral disturbance at home and at school along with a persistent learning disorder associated with an inappropriately high activity level. The clinical group children were judged not to possess an overt neurological syndrome, deafness, visual disability, or global mental retardation. Other rare but possible causes of hyperactivity such as hypoglycemia or hyperthyroidism were excluded by appropriate laboratory tests.

Data were available from mothers of 136 control and 78 clinical children, out of 278 questionnaires distributed. The control sample was composed of a nearly equal number of males as females. All ratings of male subjects were retained, and a subset of female subjects was randomly selected from the control sample to best approximate the ratio of males to females in the clinical group (3:1). Final

sample sizes at 2½-5½ years of age were 63 control and 27 clinical subjects, and at ages 5½-11, 19 control and 51 clinical children.

Method of analysis. There were three separate steps to the analysis. First, items were grouped into three clusters on the basis of their statistical consistency with other items. An overall score was then obtained for each group of items, yielding three combined scores and a fourth total score across all items. Finally, analyses of variance were performed to evaluate whether the four combined scores yielded significant differences among clinical, control, and age-varying children.

Only 26 out of the 28 items on the questionnaire proved analyzable due to an error in data collection. To determine the interrelations among these items, in the total sample of subjects, monotonicity analysis was deemed appropriate, since the item responses were binary. This procedure determines latent dimensions of variation for rank-order data, analogous to principal components analysis for interval data (Bentler, 1970). Three-, four-, and five-factor solutions were obtained and rotated to an orthogonal, simple structure orthosim criterion (Bentler, 1977). Each item was then clustered into one of three groups on the basis of which factor it most adequately assessed. Since the three-factor solution proved to be most clearly interpretable, a target rotation was performed (Bentler, 1971) and the orthogonal loadings were interpreted (Bentler, 1968).

Results

Factor computations. Factor loadings for the three-dimensional solution are presented in Table 1; these loadings summarize the extent to which each item measures each dimension. Items have been grouped into three clusters on the basis of which factor they assess best.

Three clear-cut factors emerged, showing a strong correspondence to the hypothesized dimensions. Thus, parent perceptions of normal and hyperkinetic children vary in at least three ways, so that a particular child may show any combination of behaviors from the three dimensions; within a dimension, however, if a child tends to exhibit one of the behaviors, the child tends to exhibit the others. On the whole, items tend to measure a given factor quite well and are not relevant to other factors. (Contrast the low loadings

¹ Requests for copies of the rating scales should be sent to Arnold H. Zukow, 5363 Balboa Boulevard, Encino, California 91316.

Table 1
Parent Form: Dimension Loadings

Item	<i>M</i>	Factor loading		
		1	2	3
Factor 1: Excitability				
Irritable	.45	.76	.16	.16
Quick-tempered, explosive	.60	.73	.02	.05
Overly sensitive	.49	.71	.01	.30
Emotionally high strung	.44	.68	.11	.24
Unpredictable, unmanageable	.43	.63	.20	.27
Panics easily	.30	.56	.28	.21
Poor coordination	.24	.55	.15	.24
Can't seem to keep from touching everything and everyone around him	.45	.54	.29	.37
Fidgets	.63	.42	-.02	.36
Reacts adversely to changes in routine	.29	.41	.27	.07
Factor 2: Motor Coordination				
Has trouble drawing, writing	.19	.03	.80	.17
Has trouble buttoning	.21	-.19	.78	-.03
Eyes and hands don't seem to function together	.09	.47	.70	.14
Trouble with bicycle	.13	.08	.69	.24
Exceptionally clumsy	.10	.35	.65	.12

Item	<i>M</i>	Factor loading		
		1	2	3
Factor 2: Motor Coordination				
Was slow learning to walk	.16	-.02	.63	.19
Speech development has been slow	.15	.28	.50	.01
Factor 3: Directed Attention				
Is child lazy—not trying to do well in school?	.19	.18	.17	.82
Daydreams while doing homework assignments	.24	.20	.08	.82
Not learning in school although seems "bright"	.24	.14	.22	.77
Knows work orally at home—gets to school and has to write it down—fails.	.14	.16	.25	.75
Short attention span	.53	.31	.20	.59
Tolerance for failure and frustration is low	.64	.40	.08	.56
Jumps from one activity to another	.45	.24	.12	.52
Unusually hyperactive	.48	.45	.13	.49

Note. Those factor loadings that are considered to define a given factor appear in italics.

on irrelevant factors.) In some cases, items appear to be falling in between two factors, as indicated by a high loading on two factors; such items are ignored in factor interpretation.

The items defining the first factor appear similar to those marking hyperactivity as described by others. It is an excitability factor concerned with both the quality and quantity of behavior, including perpetual motion accompanied by explosive outbursts. The second factor refers to motor coordination exclusively. Items include general descriptions of poor coordination and more specific delays and difficulties with buttoning, walking, draw-

ing, speech, and so on. Finally, the third factor refers to directed attention or sustained participation in goal-directed behaviors. The items deal with motivation, attention/control, and learning as perceived by the parent. All item means are given in Table 1, which shows the relative proportion of children considered to exhibit a given behavior.

Factor scores. Once the three factors had been extracted, a score was computed for each child on each factor. The items whose loadings are italicized in Table 1 were used to compute three factor scores, with Factor 1 being measured by nine items, Factor 2 by seven items, and Factor 3 by seven items.

Scores were obtained by adding a point for every yes response. The three factor scores proved to be an adequately internally consistent, as measured by coefficient alpha, index representing the extent to which items are measuring the same dimension. Obtained alphas were .84, .74, and .82 for the three factors, respectively. To assess whether the three scores measured somewhat different aspects of behavior, the intercorrelations among the scales were obtained. In the combined sample of 160 children, the correlations were .30, .58, .30 among Factors 1 and 2, 1 and 3, and 2 and 3, respectively. These correlations are sufficiently low relative to the internal consistencies, so one can conclude that the three factors are reliably measuring distinct aspects of behavior. On the other hand, the significant and positive correlations among all three scores suggests that all items measure something in common, which, according to our experimental procedures, should involve the differentiation of hyperkinetic children from controls. Consequently, a fourth score was obtained as the sum of the previous three scores.

In addition, the two items of Table 1 not included in the three separate factor scores were included in this total score. Since "poor coordination" was deemed inconsistent with the interpretation of the other items marking Factor 1, that item was excluded from the computation of the factor total score. In view of the clear-cut nature of Coordination (Factor 2) and the absence of a high loading of the poor coordination item on Factor 2, it is apparent that parents interpreted this item as reflecting more globally on the quality of activity rather than to a specific motor task as might be expected, nor did parents interpret this item in terms of inattentiveness as reported by Conners (1969). The item "unusually hyperactive" loaded quite similarly on Factors 1 and 3 and therefore was not included in either factor score. Even though these two items do not clearly define a given factor, they do contribute to the overall description of hyperkinetic behavior. Thus these two items are included along with all italicized items of Table 1 in the computation of the fourth, total score. Its internal consistency

^a *df* = 1.^b *df* = 156.* *p* < .05.** *p* < .001.

was .89, higher than the three separate scores, so that this score provides the most reliable overall description for these children. There are thus four scores for each child. The scores were examined for group mean differences.

Group comparisons. The parent form discriminates among clinical and control status at statistically significant levels. The statistical analyses are presented in Table 2. Each of the three factors, as well as the total score, verifies the statistically higher means obtained by clinical subjects as compared with control subjects. As expected, the total score yields the most reliable differentiation. In only one case was there a significant effect of age of subjects on the scores. This occurred in the third scale, concerned with directed attention. The effect is quite minimal in significance level compared to subject status, however, and can only be interpreted simultaneously with the interaction effect. Even though among the clinical group older subjects received higher scores, among the controls the age trend was minor and reversed.

Cross-validation. Results from preliminary work in cross-validation showed that among 26 clinical subjects (3½–14 years old),

all four factor scores on the parent rating scales were significantly different ($p < .001$) from the original control subjects. In all cases the direction of the differences and the size of the difference was virtually identical to that reported in the original study. A comparison of the original clinical group means to the means of the new clinical subjects revealed a high degree of similarity. More studies to substantiate this finding are indicated.

Classification. The task of differentiating clinical from control subjects can be accomplished by using the total scores, with cutoff scores being determined to maximize correct classification. Children receiving scores of 0–8 can be labeled as *normal*, whereas those scoring 9 or more can be labeled as hyperkinetic. Comparing the “true” status of the children, as determined by pediatrician judgments, with the labels obtained solely by the cutoff score yields the following picture: Ninety-six percent of the 90 young subjects were correctly classified, and 90% of the 70 older subjects were correctly classified. A more detailed look at the younger subjects reveals that 89% of the clinical subjects and 98% of the controls were correctly classified. Among the older subjects, 90% of the clinicals were correctly identified, as were 89% of the controls. These percentages are quite encouraging, compared to the 70%–80% figures reported in similar studies (Conners, 1970). Among the cross-validated clinical subjects, the cutting score of 8/9 correctly identified 81% of the children. This decrease in classification accuracy is a typical concomitant of cross-validation, but fortunately the results demonstrate that the instrument can be expected to be successfully applied in future studies.

Teacher Form

Method

Initial item pool. The rationale for the teacher form followed that of the parent form, but it was necessary to limit the size of the item pool due to time demands on teachers. A total of 15 items were devised to represent a broad range of school activities: tapping, motor skills, attention, and impulsive/explosive behavior. To introduce sufficient variance into the responses, teacher ratings were made on a 5-point scale.

Subjects. A new set of subjects, consisting of 78 controls and 36 clinical subjects, participated. Subject selection is described under *Parent Form*. An attempt was again made to sample a broad age spectrum. Sample sizes at ages 2½–5½ were 22 and 11 for controls and clinicals, respectively. At ages 5½–11, the corresponding sample sizes were 53 and 25.

Method of analysis. Steps analogous to those reported for the parent form were carried out for the teacher form. Since the data were adequately continuous rather than binary, a traditional least squares factor analysis was undertaken. Initial communality estimates were squared multiple correlations. Two different factor analyses were undertaken, a three-factor solution and a two-factor solution. The first three eigenvalues of the three-factor solution were 8.03, 1.15, and .82, suggesting that two factors or even one factor might be sufficient to account for the item intercorrelations. Rotation of the three-factor solution yielded two interpretable factors and a third unclear factor. The two-factor solution, rotated by orthosim, in contrast, yielded the same two interpretable factors.

Table 3
Teacher Form: Factor Loadings

Item	Factor loading	
	1	2
Factor 1: Attention/Excitability		
Is attention span short?	.83	.33
Child fidgets	.78	.30
Is the child a behavioral problem in class?	.78	.22
Unable to follow directions?	.73	.40
Quick-tempered, explosive	.67	.20
Seems to touch everything and everyone around him	.66	.31
Finds it hard to play with his peers	.65	.37
There are no activities that the child can focus his attention on	.62	.56
Has a low tolerance for failure and frustration	.61	.38
Reacts adversely to changes in routine	.60	.39
Factor 2: Motor Coordination		
Exceptionally clumsy	.20	.89
Coordination is poor	.32	.85
Speech development is slow or not clear	.16	.55
Eyes and hands can't seem to function together	.37	.53
Quiet and withdrawn—a loner	.19	.40

Note. Factor loadings that contribute to the total score for each factor appear in italics.

Results

Factor computations. Factor loadings for the two-factor solution are presented in Table 3. As before, items have been grouped into two clusters on the basis of which factor they best assess. The content of the items suggests that the first factor deals with attention and excitability, combining the two separate parent factors. It seems to represent the classical aspects of hyperactivity noted for the hyperkinetic syndrome. Factor 2, mirroring the content of the second parent factor, deals with motor coordination.

Factor scores. A score was determined for each child on each factor by summing the rating score given a child for each item in a given factor. A third total score was obtained analogously to the parent form by summing across the two factor scores and, in addition, including the item dealing with inability to focus continuously on any one activity; that item had been omitted from the two separate scores because it falls between the two factors. An internal consistency coefficient was obtained for each dimension, and the intercorrelation among the two factor scores was obtained in the combined total sample.

The internal consistency coefficients were again sufficiently high to reinforce the concept that the items comprising the two factor scores are measuring something in common. The alpha coefficients of .93 and .81 were compared to the intercorrelation of .63 between the scores on the two factors, which is again sufficiently low to consider the two factor scores to be measuring an independent aspect of behavior. On the other hand, the correlation of .63 is sufficiently high to assure that the scores measure the common tendency toward hyperkinesis, as indexed by coefficient alpha of .94 for the 15-item total score.

Group comparisons. The teacher form discriminates among clinical and control status at statistically significant levels. Factor scores are able to discriminate between clinical and control subjects. The subject status column of Table 4 indicates that the clinical means were significantly higher than

Table 4

^a $df = 1$.

^b $df = 107$.

* $p < .05$.

** $p < .001$.

the control means in all of the comparisons at a high level of significance. There appears to be no age effect at all, and in only one case was the interaction of subject status and age statistically significant. As before, this interaction suggests that scores for clinical children increase with age, whereas those of control children do not.

Cross-validation. Results from the preliminary cross-validation of the teacher form paralleled the findings from the preliminary cross-validation of the parent form. Significant differences were found between the 26 new clinical subjects and the original control group ($p < .001$).

Classification. Children with a score of 35 or less can be classified as "normal"; those receiving a score of 36 or more can be classified as "hyperkinetic." Among the 33 younger subjects, 70% were correctly classified, whereas 85% of the 78 older subjects were appropriately grouped. The cutting score of 35/36 correctly classified 85% of the new clinical subjects.

Discussion

The factors that emerged in the parent and teacher forms indicated that both parents and teachers differentiated the excitability/attention versus motor coordination as-

pects of hyperkinesis. However, the analysis of the parent form revealed that parents differentiated excitability and directed attention as well. It is possible that this result is an artifact of the items used in the two studies. A careful analysis of the item pools indicates that the content concerned with daydreaming, not doing well in school, and so on, was omitted from the school form. In future versions of the instrument, item tapping this content will be included.

Although the factor loadings make it appear extremely likely that the factors from the two instruments are similar, there was no way in this study of verifying or disproving this hypothesis. Strict similarity can be verified by the demonstration of a high correlation between scores obtained on the parent form and the comparable scores on the teacher form. Unfortunately, the design of the current studies did not allow data to be obtained from both parent and teacher sources on the same subjects, so a correlation coefficient could not be computed. Even though a significant correlation between the parent and teacher factors might be expected, parents, teachers, and others actually have different sources of observational data about a child. It is quite possible that there may be little agreement regarding, say, concentration problems. The teacher may be in a better position to observe such characteristics in the classroom. A further study on this issue is clearly called for.

Langhorne et al. (1976) had the data to correlate composite teacher ratings, chart ratings, psychiatrist diagnosis, and parent ratings but, unfortunately, did not report on the extent of agreement that might be observed using such composite ratings. As pointed out before, since their analyses were based on an arbitrarily selected, very small subset of their data, it is not possible to rely on their conclusion that there is little or no agreement among sources of data. It is possible that among the many items discarded from their analysis, there may have existed numerous items showing high agreement across data sources.

The factors that did appear in this study were similar to those found by previous workers. The teacher form attention/excitability

factor was very similar to the hyperactivity factor reported by Blunden et al. (1974), as well as to the hyperactivity factor identified by Conners (1969). Results from the present parent form lend support to Conners' (1969) finding that an inattentiveness factor is distinct from impulsivity/hyperactivity. Further, our results show a clear separation between directed attention, including distractibility and concentration difficulties and poor motor coordination. Items from these two categories were not well represented in previous research, as indeed some were absent from the current teacher form. Obviously, items dealing with other content material, such as social behavior, also deserve further study and should be included in future research on this topic.

Numerous researchers have emphasized the disappointing results found in many studies investigating the effect of medication (Whalen & Henker, 1976) and/or psychological (Gittelman-Klein et al., 1976; O'Leary et al., 1976) or educational therapy (Douglas, 1974; Keogh & Margolis, 1976) on academic achievement. Some of these findings may be attributed to the problem of obtaining sufficient homogeneity among subjects, as recently reviewed in Langhorne et al. (1976). For example, the criteria for subject selection in studies of hyperkinetic children is often quite global (Keogh & Margolis, 1976; Rie et al., 1975). Furthermore, the variation of criteria for subject selection precludes generalization of results from study to study.

A preliminary investigation on the effectiveness of medication as a function of initial scores on the instruments yielded mixed and somewhat disappointing results. Of the 20 possible correlations, two were statistically significant. Statistically significant correlations of .68 and .75 ($p < .02$) were found between clinical rankings of medication effectiveness and Factor 1 of the teacher form and the total score in a sample of nine children under 5½ years of age. The children most responsive to medication were those initially considered by teachers to be most disturbed in excitability or in combination with poor coordination. Since there have been few reliable predictors of responsiveness to medication (Ross & Ross, 1976),

this encouraging result is being investigated further.

The total factor score derived from the parent and teacher rating scales permits the accurate identification of subjects, although it must be admitted that the issue of differential diagnosis also merits future research. Scores on the individual factors may provide a vehicle for investigating differential diagnosis and examining potential relationships between particular treatment conditions and changes in disapproved behavior, academic performance, cognitive abilities, and social skills. There is a striking similarity between the factors that emerged in this analysis and aspects of attentional disorders observed and described by several research groups. Douglas (1972, 1974) has characterized the facets of attention necessary for adequate academic performance as the ability to focus, to inhibit impulsive responding, and to sustain and organize attention; that is, to "stop, look, and listen"; Keogh and Margolis (1976) as coming to attention, problem solving, and maintaining attention; and Whalen and Henker (1976) as differences in ability to modify motor behavior to meet situational demands, in socially adaptive behaviors including impulsivity, and in sustained attention. Although the components of attention proposed by these researchers are not isomorphic and probably not entirely independent, the individual factor scores might perform the important function in future research of providing an objective basis for subject selection for various treatment conditions and for assessing changes in behavior and performance. The relationship between the parent and teacher rating scales and the Margolis-Keogh children's checking task is currently under investigation to provide further validation of the scales.

In conjunction with the researcher's or clinician's own observations, these instruments fulfill the function for which they were designed—to provide supplementary information and to serve as a guide for the conscientious clinician or researcher in the identification and treatment of hyperkinesis (Frankenburg, 1974).²

Imagery Assessment Through Self-report: What Do Imagery Questionnaires Measure?

Merrill Hiscock
University of Texas, Austin

Assessment difficulties have impeded progress in evaluating the therapeutic role of visual imagery. Four studies examined imagery questionnaires and addressed the issues of (a) reliability; (b) agreement among different questionnaires; (c) social desirability; and (d) construct validity. The Betts and Gordon scales, and a newer inventory, the Paivio Individual Differences Questionnaire, were examined. Reliability of the Paivio inventory was found to be satisfactory and equivalent to that of other imagery questionnaires. In two studies, the Betts and Paivio questionnaires were correlated at the .45-.50 level, but correlations involving the Gordon scale were inconsistent from one study to the next. In general, imagery measures were not influenced by social desirability. Factor analysis indicated that subjective and objective measures of visualization are independent. The final study revealed a relationship between imagery questionnaire scores and reported values and interests. It is suggested that imagery is not a unitary construct and that criteria other than visuospatial tests may be appropriate for validating imagery questionnaires.

The emphasis on imagery in otherwise dissimilar therapeutic techniques (e.g., Horowitz, 1970; Wolpe & Lazarus, 1966) suggests that understanding imagery may be as useful in clinical practice as in the learning laboratory (cf. Paivio, 1971). Behavior therapy techniques, in particular, frequently include instructions directing the client to imagine specified aversive or reinforcing stimuli. Substituting imagery instructions for in vivo presentation of stimuli is more than a matter of convenience, for imagery instructions potentially enhance the flexibility and power of various techniques (Cautela, 1971). However, it is not known to what extent imagery actually medi-

ates the obtained results; research has failed to establish a relationship between therapy outcome and self-reported individual differences in imagery (Beere, 1972; Davis, McLemore, & London, 1970; McLemore, 1972). Either therapeutic success is independent of ability to form images or the expected relationship is obscured by inadequate measurement of individual differences in imagery.

The assessment problem is difficult. It is not clear what imagery questionnaires really measure or what criteria are appropriate for validating them. Objective tests of spatial ability appear to share little or no variance with visual imagery questionnaires (Di Vesta, Ingersoll, & Sunshine, 1971; Forisha, 1975; Neisser, 1970; Paivio, 1971, p. 496), and no consistent relationship has been established between questionnaires and objective measures of memory for objects (cf. Danaher & Thoresen, 1972; Marks, 1972; Rehm, 1973; Rimm & Bottrell, 1969). In fact, it has been argued that the subjective experience of imagery bears little relationship to any measurable capacity (Neisser, 1970). Reliable physiological correlates of subjectively reported imagery are equally elusive (see Paivio, 1971, 1973; Richardson, 1969).

The author is indebted to Regina Hilbertz, Steve Jackson, Randy Routon, and Charlotte Wilson for their assistance in data collection; to David B. Cohen and an anonymous reviewer for their helpful comments and suggestions; to Lyle Freedman for making available the questionnaire data from the group of 114 subjects in Study 1; and to Ginger Hiscock and Leota Servetnyk for their assistance in preparing the manuscript.

Requests for reprints should be sent to Merrill Hiscock, who is now at the Division of Psychology, University Hospital, Saskatoon, Saskatchewan, Canada S7N 0W8.

The questionnaires themselves have received relatively little critical attention despite their probable psychometric shortcomings. Rating scales such as Sheehan's (1967b) version of the Betts Questionnaire upon Mental Imagery (reprinted in Richardson, 1969) and Marks's (1973) Vividness of Visual Imagery Questionnaire require subjects to judge their images using a numerical scale on which one pole always represents "good" imagery. This format is very susceptible to response sets (see Mischel, 1968). The same criticism can be leveled at the Gordon (1949) scale of imagery control (reprinted in Richardson, 1969) on which a yes response always indicates controllable imagery. In fact, Di Vesta et al. (1971) found that the factor that loaded on the Betts and Gordon questionnaires also loaded on the Marlowe-Crowne Social Desirability Scale (Crowne & Marlowe, 1960). This finding is troublesome, since it suggests the possibility that any relationship between therapeutic outcome and self-reported imagery merely reflects an underlying response set that influences both imagery reports and response to therapy.

The present research addresses four fundamental issues regarding imagery questionnaires: (a) internal consistency and retest reliability; (b) agreement among different subjective measures; (c) the influence of social desirability; and (d) construct validity. Attention is focused on an inventory—Paivio's (1971) Individual Differences Questionnaire (IDQ)—as a possible alternative to the traditional rating scale.

Study 1

Method

Subjects. As in the three subsequent studies, subjects were undergraduate students enrolled in introductory psychology courses at the University of Texas at Austin. Three groups of subjects participated in Study 1. One group comprised 48 females, the second comprised 114 subjects with an approximately equal number of females and males, and the third group comprised 43 females and 36 males.

Procedure. The first steps taken were to evaluate and improve Paivio's IDQ, which is an 86-item true-false instrument requiring respondents to report their characteristic "ways of thinking, studying, and problem solving." The questionnaire yields two scores: one for imagery and one for verbal processes. The directionality of scaling for several items is reversed to minimize the effect of agreement or acquiescence.

The IDQ was completed by the first two groups of subjects. Item-scale correlations were computed to identify nonproductive items; 15 items whose correlation with the respective scale score was less than .25 for both groups was excluded from the revised questionnaire. After 1 new item was added, the revised questionnaire contained 38 verbal and 34 imagery items. The format was changed to a Likert scale format with five available responses per item.

The 72-item IDQ was administered to the third group of subjects, and Cronbach's alpha (Cronbach, 1951) was computed to assess internal consistency. Fifty-eight (73%) of the 79 subjects completed the questionnaire a second time 2–6 weeks after initial testing. The scores of these subjects provided a basis for estimating retest reliability.

Results

Scores for both IDQ scales were distributed in Gaussian manner. Cronbach's alpha for the Imagery scale of Paivio's original questionnaire was .80 for the first group and .81 for the second group of subjects. The same statistic for the 72-item version was .87 for the group of 79 subjects. The Verbal scale yielded similar values of alpha: .83 and .86 for the original questionnaire and .88 for the 72-item version. Retest reliability coefficients for the 72-item IDQ were .84 for the Imagery scale and .88 for the Verbal scale.

Study 2

Method

This study addressed two issues: (a) the degree of association among the Paivio IDQ, Sheehan's version of the Betts Questionnaire upon Mental Imagery, and the Gordon scale of (visual) imagery control and (b) the correlation between each of these instruments and the Marlowe-Crowne Social Desirability Scale. A sample of 123 undergraduates (68 females, 55 males) completed the 72-item IDQ, the Visual and Auditory scales of the Betts questionnaire, and the Gordon scale. All but 10 of these subjects also completed the Marlowe-Crowne Social Desirability Scale. Correlations were computed.

Results

Table 1 shows the correlations among the five imagery scales and between each of these scales and the Marlowe-Crowne scale. Sex of subject is also included in the intercorrelation matrix; negative correlations with sex reflect higher scores for females. The polarity of cor-

Table 1
Correlations Among Imagery Questionnaires and the Marlowe-Crowne Social Desirability Scale

Variable	2	3	4	5	6	7
1. Sex	.11	-.29**	-.04	-.33**	.03	-.20*
2. Gordon scale		.16	.10	.21*	.17	-.10
3. Betts Visual scale			.40**	.49**	.17	.09
4. Betts Auditory scale				.21*	-.15	.10
5. Paivio Imagery scale					.13	.02
6. Paivio Verbal scale						-.11
7. Marlowe-Crowne scale						

Note. $n = 123$ for all variables except the Marlowe-Crowne scale, for which $n = 113$.

* $p < .05$.

** $p < .01$.

relations involving the Betts questionnaire has been reversed to compensate for the negative scaling of that instrument. Positive associations between imagery reported on the Betts scales and other variables thus appear as positive correlations.

The strongest association indicated in Table 1 is between the Paivio IDQ Imagery scale and the Betts Visual scale ($r = .49$). Correlations between the Gordon scale and the other two visual imagery scales did not exceed .21. There was a moderately strong association between the Visual and Auditory scales of the Betts questionnaire ($r = .40$) but virtually no association between the Visual and Verbal scales of the Paivio IDQ. The Betts Auditory scale and the IDQ Verbal scale were not related.

No variable showed a correlation greater than .20 with the Marlowe-Crowne Social Desirability Scale. The variable that did correlate at the .20 level with social desirability was sex; females tended to score higher than males. Correlations between the Marlowe-Crowne scale and the five imagery scales did not exceed .11 in magnitude, and their average was exactly zero.

Correlations of $-.29$ and $-.33$ between sex and the Betts Visual scale and between sex and the Paivio IDQ Imagery scale, respectively, indicate that females report "better" imagery than do males. The means were 10.62 for females versus 12.87 for males on the Betts scale, $t(121) = 3.36$, $p < .01$, and 134.99 for females versus 126.02 for males on the IDQ, $t(121) = 3.77$, $p < .01$. Separate intercorrelation matrices were computed for females and males, but the only significant difference involved the

relationship between the Gordon scale and the Marlowe-Crowne scale. The correlation for females was $-.28$ versus .11 for males ($z = 2.05$, $p < .05$).

Study 3

Method

The 43 females and 36 males who completed the 72-item Paivio IDQ in Study 1 were given six other questionnaires and tests. Among these were the Gordon scale and the Visual and Auditory scales of the Betts questionnaire. An objective test of spatial ability, the Minnesota Paper Form Board Test, was included in the battery. This test, which has been used by Ernest and Paivio (1969, 1971) as part of an "imagery battery," represents a possible exception to the usual finding that objective tests are unrelated to imagery questionnaires (cf. Paivio, 1971, p. 496). The Quick Word Test (Borgatta & Corsini, 1960) was selected as a vocabulary test. Because of time constraints, only the first 35 items were used. The final two measures were developed specifically for use in the present study. One of these, called the Visual Memory Scale, requested subjects to imagine six common objects in the local area and then "read out" specific information from their images. For example, subjects were asked to visualize the university tower and count the columns of windows on one face. The other measure, called the Visual Manipulation Scale, required subjects to mentally manipulate various objects. A representative item from this scale, taken from Griffiths (1927), instructs subjects to picture a 3-inch (4.62 cm) cube, painted red, that is sawed into 1-inch (1.54 cm) cubes. Subjects were asked to determine the number of little cubes having paint on three faces.

All together, 10 variables were represented in the intercorrelation matrix. The three imagery questionnaires contributed a total of five scales; there were four objective tests, and subject's sex was the 10th variable. The intercorrelation matrix was factor analyzed, and the factors extracted were rotated using a varimax procedure.

Table 2
Correlations Among Subjective and Objective Measures

Variable	2	3	4	5	6	7	8	9	10
1. Sex	-.10	-.36**	-.02	-.19	-.16	.21	.10	.11	-.02
2. Gordon scale		.47**	.37**	.56**	.20	-.09	.06	-.05	-.06
3. Betts Visual scale			.43**	.46**	.05	-.16	.01	-.09	-.09

7. Visual Memory Scale							.02	.21	.03
8. Visual Manipulation Scale								.39**	.28*
9. Quick Word Test									.18
10. Minnesota Paper Form Board									

Note. $n = 79$.

* $p < .05$.

** $p < .01$.

Results

The intercorrelation matrix is presented in Table 2. Again, negative correlations with sex reflect higher scores for females, and positive correlations with the Betts scales reflect positive associations.

Relationships among the five imagery scales were similar to those found in Study 2, except that correlations between the Gordon scale and the two other visual scales were markedly stronger than those found earlier. The correlation between the Gordon scale and the Betts Visual scale ($r = .47$) was significantly greater than .16 in Study 2 ($z = 2.38$, $p < .05$), and the correlation between the Gordon scale and the Paivio IDQ Imagery scale (.56) was significantly greater than .21 in Study 2 ($z = 2.86$, $p < .01$). The IDQ Imagery scale and the Betts Visual scale again were correlated at a moderate level ($r = .46$).

Females again tended to report "better" imagery than males on the IDQ Imagery scale and the Betts Visual scale, but only the Betts scale yielded a significant sex difference, $t(77) = 3.30$, $p < .01$. The mean for females was 10.81 versus 14.28 for males. When separate intercorrelation matrices were calculated for females and males, only two significant differences were found, and both involved the Gordon scale. The correlation between the Gordon scale and the Betts Visual scale was significantly greater for males ($r = .66$) than for females ($r = .08$, $z = 2.99$, $p < .01$). Similarly,

the correlation between the Gordon scale and the Betts Auditory scale was greater for males ($r = .60$) than for females ($r = .00$; $z = 2.92$, $p < .01$).

There was no appreciable association between subjective and objective measures of imagery. The Paivio IDQ Verbal scale, however, did show a modest correlation with the Quick Word Test ($r = .30$).

Four factors with eigenvalues greater than 1.0 emerged from factor analysis. Loadings for each of these factors are shown in Table 3. Factor 1 loaded on the three visual imagery scales and the Auditory scale of the Betts questionnaire; Factor 2 loaded on the Minnesota Paper Form Board and the Visual Manipulation Scale; Factor 3 loaded on the subject's sex and the Visual Memory Scale; and Factor 4 loaded on the Paivio IDQ Verbal scale and the Quick Word Test.

Study 4

Method

This study further explored the pattern of correlations involving the Paivio IDQ. Eighty-one males completed the IDQ and three other tests. Space Relations, from the Differential Aptitude Tests (Bennett, Seashore, & Wesman, 1966), was used as an objective test of spatial ability. Like the paper form board, Space Relations is a component of the "imagery battery" used by Ernest and Paivio (1969, 1971). The Quick Word Test again served as a vocabulary test. This time all 100 items were administered.

Table 3
Factor Loadings for Four Varimax Factors

Variable	Factor				h^2
	I	II	III	IV	
Betts Visual scale	.75	-.01	-.31	.03	.66
Gordon scale	.82	.02	-.01	.16	.69
Paivio Imagery scale	.75	.04	-.13	.05	.58
Betts Auditory scale	.68	-.15	.15	-.22	.56
Minnesota Paper Form Board	-.07	.79	-.09	-.27	.71
Visual Manipulation Scale	.04	.76	.08	.25	.65
Sex of subject	-.14	.05	.79	-.20	.69
Visual Memory Scale	-.05	-.01	.70	.17	.52
Paivio Verbal Scale	.09	-.05	-.09	.88	.78
Quick Word Test	-.11	.50	.29	.56	.67
Eigenvalue	2.49	1.69	1.17	1.16	

The fourth test in the present study was the Study of Values (Allport, Vernon, & Lindzey, 1960). The imagery literature contains some evidence that characteristics of an individual's imagery are related to variables such as interests and choice of vocation (Chowdhury & Vernon, 1964; Roe, 1951). On this basis, one might expect to find a relationship between the Paivio IDQ Imagery scale and the Study of Values, which is a 45-item ipsative scale yielding a score for each of six categories of interests and values. The scale can be dichotomized into two groups of values: extraceptive (theoretical, economic, and political) versus intraceptive (aesthetic, social, and religious) (Dunn, Bliss, & Siipola, 1958). It was predicted on the basis of the Dunn et al. findings that the latter categories would be associated with visual imagery (see Paivio, 1971). Thus, rank scores for these categories were computed and summed, so that subjects who gave high ratings to these three values were assigned a high numerical score.

Results

The intercorrelation matrix is displayed in Table 4. There was no significant association between the Paivio IDQ Imagery scale and Space Relations ($r = .05$), but there was a correlation of .35 between the IDQ imagery score and the rank-order index derived from the Study of Values. As predicted, subjects who reported more frequent use of imagery tended to have high aesthetic, social, and religious scores. Other correlations involving the IDQ Imagery scale were trivial.

Two other coefficients in the matrix are notable. The correlation of .41 between the IDQ Verbal scale and the Quick Word Test replicates a finding of Study 3. Also, the Quick Word Test and Space Relations were associated at the .29 level.

Discussion

The formal psychometric properties of Paivio's IDQ that were evaluated were found to be satisfactory. Even though reverse scaling of several items should have counteracted response sets that might inflate a reliability estimate, retest reliability appears to be at least comparable to that of the shortened Betts questionnaire (Sheehan, 1967a) and Marks's (1973) Vividness of Visual Imagery Questionnaire.

The instability of correlations involving the Gordon scale requires explanation, especially since McLemore (1976) recently reported very similar findings. Also, the only differences between the intercorrelation matrices for females and for males involved the Gordon scale. An estimate of retest reliability is not available; but split-half reliability of the Gordon scale is reasonably good ($r = .77$ for Study 2 and .84 for Study 3). A more probable source of difficulty is the marked skewness of the frequency distribution. A concentration of scores at the high end of the scale allows a relatively small number of low scores to exert disproportionate influence on correlations with other measures. Consequently, correlations vary between samples. Since the modal score is the maximal score (12 yes responses), transformations are not of much help. Moreover, the departure from normality will affect the bivariate distribution on which the product-moment correlation is based, and it may bias the z statistic used to assess the significance of differences between cor-

Table 4
Correlations among Space Relations, Study of Values, Quick Word Test, and the Paivio Individual Differences Questionnaire

Variable	2	3	4	5
1. Space Relations	.02	.29*	.05	.00
2. Study of Values		.08	.35*	.09
3. Quick Word Test			-.04	.41*
4. Paivio Imagery scale				.11
5. Paivio Verbal scale				

Note. $n = 81$ males.

* $p < .01$.

relations. Although the Gordon scale may be of some use in selecting cases for experimental or clinical purposes, it should either be modified (cf. Lane, 1975) or avoided in correlational and factor-analytic studies.

A milder degree of skewness in the distribution of scores on the Betts scales does not seem to affect this test's stability. On the contrary, correlations between the Betts scales and other variables (except the Gordon scale) proved to be remarkably stable from Study 2 to Study 3. Although the probable contribution of method variance cannot be overlooked (Mischel, 1968), the correlation between the Betts Visual scale and the IDQ Imagery scale suggests the existence of some subjective dimension that can be tapped using instruments that differ in format and content.

However, Di Vesta et al. (1971) concluded that subjective measures of imagery lack construct validity. There was no substantial correlation between imagery questionnaires (i.e., Betts's and Gordon's) and spatial tests, and the factor that loaded on the imagery questionnaires also loaded on the Marlowe-Crowne scale. Present data failed to support the Di Vesta et al. finding regarding social desirability, but perhaps the disparate evidence can be reconciled. First, Di Vesta et al. may have created a "method factor" by adding imagery questionnaires and the Marlowe-Crowne scale to a battery of objective tests. Second, even if the Betts Visual and Auditory scales are not contaminated by social desirability, some of the other Betts scales might be (cf. McLemore, 1976). Third, the general instability of correlations involving the Gordon scale could ac-

count for apparent differences in the influence of social desirability.

The present data support the Di Vesta et al. (1971) conclusion that imagery questionnaires and spatial tests are not interchangeable. Studies 3 and 4 demonstrate the kind of dissociation between self-reports and performance that led Neisser (1970) to argue that the accuracy or usefulness of imagery is unrelated to the subjective experience of imagery. It is especially interesting that the Betts Visual scale and the Visual Memory Scale were unrelated. Even subjects who reported the clearest and most vivid images were no more able than subjects on the other extreme of the Betts distribution to read out accurate information about visual aspects of familiar objects (cf. Woodworth, 1921, p. 372).

If imagery questionnaires are not contaminated by response sets, and nevertheless are unrelated to visuospatial performance, perhaps it is because imagery is not a unitary construct. That which imagery questionnaires measure may be different from, but no less interesting than, that which visuospatial tests measure. However, questionnaire validity still needs to be demonstrated. Two possibilities present themselves as potential criteria for validating imagery questionnaires. The first is performance on certain verbal memory tasks. Paivio (1971) has suggested that "an acquired disposition of the individual to react to words (especially concrete words) with nonverbal images" (p. 509) can be measured by questionnaires. Consistent with Paivio's conception the 72-item IDQ proved to be useful in predicting recall of high-imagery adjectives from prose (Hiscock, 1976). Study 4 suggests a second possible correlate of self-reported imagery. The obtained correlation of .35 between the IDQ Imagery scale and the Study of Values is not strong, but the relationship is consistent with previous findings (Chowdhury & Vernon, 1964; Dunn et al., 1958; Roe, 1951), and it demonstrates the need for more attention to values, interests, and choice of occupation as potential correlates of subjective imagery.

Two additional implications of the present research merit consideration. The first concerns the orthogonality of the Imagery and Verbal scales of the Paivio IDQ. Apparently, being a "verbalizer" is not simply the reciprocal

of being a "visualizer." For some purposes, especially studies of the relationship between imagery and language, the IDQ may prove most useful when it is used to select subjects on the basis of high scores on one scale and low scores on the other. The second observation pertains to sex differences. Females tend to score higher than males on the Betts Visual scale and the Paivio IDQ Imagery scale, and, in at least two imagery studies (Ernest & Paivio, 1971; Marks, 1973), females have outperformed males. Ernest and Paivio (1971) proposed that "in some tasks, females 'use' imaginal processes to facilitate recall whereas males do not" (p. 71).

No imagery questionnaire is likely to be the best choice for all applications. Paivio's IDQ promises to be a useful instrument for investigating habitual styles of information processing and, in particular, for investigating the manner in which people internally represent words. Consequently, it should be useful for studying the relationship of imagery to attitudes, interests, career choices, and so on. The IDQ thus offers a means of validating the concept of visual imagery as a cognitive style. The therapist, however, may prefer to have a "state" measure rather than a "trait" measure of imagery (McLemore, 1976). In this case, and also when nonvisual (e.g., tactile) imagery is of interest, a rating scale may be the only appropriate device.

INSTRUCTIONS TO AUTHORS

Style of manuscripts. Manuscripts must be prepared in the style described in the *Publication Manual of the American Psychological Association* (2nd ed.). Instruction on tables, figures, references, metrics, and typing (all copy must be double-spaced) appear in the Manual. Authors should submit manuscripts in triplicate and should keep a copy to guard against loss.

Abstracts. Manuscripts of regular articles must be accompanied by an abstract of 100-175 words. Manuscripts of brief reports must be accompanied by an abstract of 75-100 words. All abstracts must be typed on a separate sheet of paper.

Brief Reports. The *Journal of Consulting and Clinical Psychology* will accept Brief Reports of search studies in clinical psychology. The procedure is intended to permit the publication of soundly designed studies of specialized interest or limited importance which cannot now be accepted as regular articles because of lack of space. Several pages in each issue will be devoted to Brief Reports, published in the order of their receipt without respect to the dates of receipt of the regular articles. Most Brief Reports appear in the first or second issue to go to press following their final acceptance.

An author who wishes to submit a Brief Report:

1. Sends the Brief Report, limited to two printed pages and prepared according to the specifications given below.

2. Agrees not to submit the full report to another journal of general circulation.

Specifications. The Brief Report should give a clear, condensed summary of the procedure of the study and as full an account of the results as space permits.

To ensure that a brief report does not exceed two printed pages, follow these instructions for typing: (a) Set typewriter to a 48-space line. (b) Type text. (c) Count all lines except abstracts, title, and by-line, including acknowledgments. If you have exceeded 185 lines, shorten the material. (d) If your brief report barely exceeds 75 lines (one printed page), try to edit to 75 lines exactly. Reports slightly exceeding one page will be edited for length in order to use space economically.

In Brief Reports, headings, tables, and references are avoided or, if essential, must be counted in the 75 lines. This journal no longer requires an extended report, but, if one is available, each Brief Report must be accompanied by the following footnote:

Requests for reprints and for an extended report of this study should be sent to John Doe (give the author's full name and address).

The footnote should be typed on a separate sheet and *not* counted in the 75-line quota.

A Model of Psychopathology Based on an Integration of MMPI Actuarial Systems

Harvey A. Skinner
Addiction Research Foundation,
Toronto, Ontario, Canada

Douglas N. Jackson
University of Western Ontario,
London, Canada

Relationships among Minnesota Multiphasic Personality Inventory (MMPI) code types from the Gilberstadt and Duker and the Marks, Seeman, and Haller systems were evaluated using an empirical clustering procedure. Three superordinate types were identified: neurotic (*Hs*, *D*, *Hy*), psychotic (*Sc*, *Pt*), and sociopathic (*Pd*, *Ma*), which form a theoretical model of psychopathology. Patients can be readily classified according to this typology and a graphic display of the results constructed. The importance of differentiating profile elevation, scatter, and shape is discussed when matching a given MMPI profile to the various code types. The data from the MMPI do not support the practice of highly differentiated classification within the three superordinate types.

In recent years there has been considerable interest in the development of actuarial systems for test interpretation in clinical settings. The Minnesota Multiphasic Personality Inventory (MMPI) systems of Gilberstadt and Duker (1965) and of Marks, Seeman, and Haller (1974) are two well-known examples. Potential advantages of such systems include economy of description, use of previous information and experience accumulated for specific code types, and the facility for automating test scoring and interpretation to save the clinician valuable time. Thus, given the MMPI profile for a patient, the clinician can determine if this profile matches a specific code type. The implicit assumption is that information garnered for this code type applies, more or less, to this patient.

The Gilberstadt and Duker (1965) system has 19 prototypes that were identified using

the "classic case" approach. Marks et al. (1974) developed 16 adult code types by examining profile configurations in a sample of psychiatric patients. Although each system was developed using a different rationale, one immediate question is the degree of overlap between the two approaches. A second issue concerns the actual steps used in classifying a profile. For example, would it be profitable to examine the independent contribution of profile elevation, scatter, and shape (Cronbach & Gleser, 1953; Skinner, 1977) as a means of improving classification hit rates? Payne and Wiggins (1968) found that either system only classifies approximately 28% of a psychiatric hospital sample, whereas joint application resulted in an overall hit rate of 49%. This percentage will vary apparently as a function of the educational level of the patient population.

This article investigates empirically the degree to which MMPI profiles can be conceptualized in terms of three superordinate MMPI types (neurotic, psychotic, and sociopathic). A second aim is to evaluate the degree to which the Gilberstadt and Duker (1965) and the Marks et al. (1974) code type systems can be integrated in terms of such superordinate types. These three prototypes can be conceptualized as "ideal type constructs" (Hempel, 1965, chap. 7) that form a theoretical model of psychopathology, as assessed by the MMPI. In

This research was supported by Canada Council Grant S75-0495 IX to the University of Western Ontario and by the Addiction Research Foundation of Ontario.

The authors thank Lewis R. Goldberg and Richard I. Lanyon for providing punched data for MMPI groups.

Requests for reprints should be sent to Harvey A. Skinner, Addiction Research Foundation, 33 Russell Street, Toronto, Ontario, Canada M5S 2S1.

addition, this theoretical model offers certain practical advantages for classification research in clinical settings. The end result for classified patients is a set of elevation, scatter, and shape parameters that can be computed readily with a small calculator. Furthermore, graphic plots of the classification data can be constructed to facilitate interpretation.

Method

Subjects

The 35 MMPI code type profiles, 19 from Gilbertstadt and Duker (1965) and 16 (adult) from Marks et al. (1974), were keypunched for computer processing. Then, relationships among these 35 code types were examined using a multivariate classification strategy. Thus, the 35 MMPI code types formed the derivation sample for a new MMPI taxonomy.

To provide an estimate of the generalizability of this new MMPI taxonomy, data taken from Lanyon (1968) were classified. Lanyon has compiled mean MMPI profiles (*T* scores) for 233 diverse psychiatric and normal groups.

Procedure

Conceptually, one begins by hypothesizing that a set of ideal personality types (Hempel, 1965, chap. 7) underlie the two MMPI codebook systems. The basic concept is a modal profile, which can be defined as a hypothetical MMPI profile pattern that is characteristic of a subset of patients in a psychiatric population. Our

approach is based on the assumption that patients can be differentiated into relatively homogeneous classes by grouping those individuals who substantially resemble the same MMPI modal profile.

A least squares estimate of the modal profiles is derived through a generalized principal-components model. Jackson and Williams (1975) and Skinner (1977, in press; Skinner, Note 1) have provided discussions of this classification procedure from somewhat different perspectives. Briefly, consider a data matrix X_i giving the scores of N individuals from sample i on the 13 MMPI clinical scales. The classification model can be depicted as

$$X_i = f\{M_i, S_i, A_i P' + E_i\}. \quad (1)$$

That is, relationships among MMPI profiles (row vectors) of sample i can be expressed as a function of (a) a column vector of profile elevation parameters M_i , (b) a column vector of scatter parameters S_i , and (c) a matrix of shape parameters A_i describing the extent to which each individual's MMPI profile resembles the shape of the MMPI modal profiles. Note that shape describes the actual pattern of "ups and downs" across the 13 MMPI clinical scales and elevation depicts the degree to which the MMPI profile as a whole has high (or low) *T* scores, whereas scatter represents how dispersed the 13 scale scores are about their average (Cronbach & Gleser, 1953). Finally, E_i is a residual matrix that provides a measure of how well the modal profiles "fit" the particular sample X_i .

The present study focuses first on estimating the underlying "ideal types" or modal profiles defined by the matrix P . The 35 Code Types \times 13 MMPI Clinical Scales data matrix X was decomposed according to the Eckart and Young (1936) theorem (i.e., $X = F \Delta P'$). A least squares estimate of the modal profiles is provided by the right-hand eigenvectors P . Then, given the

Figure 1. Neurotic modal profile and a somatization reaction group Minnesota Multiphasic Personality Inventory profile.

Figure 2. Psychotic modal profile and a paranoid schizophrenic group Minnesota Multiphasic Personality Inventory profile.

modal profiles *P*, the second aim of this study is to determine the degree to which the modal profiles are representative of the 233 Lanyon (1968) MMPI groups. Basically, one is fitting the model described in Equation 1 to the Lanyon data, in which each group MMPI profile is considered as a single entity.

In a previous study using this classification model, eight modal profiles based on a structured inventory of psychopathology were identified and replicated across three samples of alcoholic patients (Skinner, Jackson, & Hoffmann, 1974). The generalizability of these modal

profiles to diverse psychiatric and normal populations was explored by Skinner, Reed, and Jackson (1976).

Results

Essentially, the analysis considered similarity in profile shape among the 35 MMPI code types to identify a set of most representative MMPI profiles. Three modal profiles were derived (Table 1) and are plotted in Figures 1-3.

Figure 3. Sociopathic modal profile and a male narcotic addicts group Minnesota Multiphasic Personality Inventory profile.

Table 1
*Minnesota Multiphasic Personality
 Inventory Diagnostic Prototype
 Modal Profiles*

Scale	Modal profile		
	1	2	3
<i>L</i>	-.670	-1.509	-.820
<i>F</i>	-1.060	.596	-.171
<i>K</i>	-.256	-1.832	.093
<i>Hs</i>	1.716	-.580	.053
<i>D</i>	1.612	.655	-.563
<i>Hy</i>	1.665	-.561	.747
<i>Pd</i>	.059	.493	2.043
<i>Mf</i>	-.561	-.683	-.467
<i>Pa</i>	-.732	.705	-.068
<i>Pt</i>	.396	1.153	-.757
<i>Sc</i>	-.311	1.832	-.305
<i>Ma</i>	-1.255	-.125	1.886
<i>Si</i>	-.603	-.145	-1.671

Note. Each modal profile has a mean = .0 and standard deviation = 1.0. Table 1 corresponds to Matrix *P* in Equation 1.

In Table 1 the data have a mean of 0 and variance of 1, whereas each modal profile is scaled in the figures to have a mean of 50 and a variance of 10. Note that the modal profiles in Table 1 correspond to the matrix *P* of the general model depicted in Equation 1. Table 2 presents the various code types with their elevation, scatter, and three shape parameters. The first modal profile, with high points on *Hs*, *D*, and *Hy*, classifies the neurotic code types from each system. For example, the Gilberstadt and Duker (1965) codes 1-3-2 and 1-2-3-7, and the Marks et al. (1974) code 2-3-1 are the purest exemplars of this *neurotic* ideal type. The second modal profile has high points from *Sc* and *Pt*. The best code type exemplar for this *psychotic* ideal type is the code 8-6 from each system. Finally, the third modal profile, labeled *sociopathic*, is characterized by *Pd* and *Ma*. Not surprisingly, the code 4-9 from each system has the highest weight.

The weightings in Table 2 describe the correlation of each codebook type with the three modal profiles of Table 1. Thus, these weightings emphasize conformance in profile *shape*, that is, the actual pattern of ups and downs across MMPI scales (Matrix *A*, in Equation 1). A second important aspect of profile resemblance is *elevation*, which is defined as the pa-

tient's average across the 13 MMPI scales (Vector *M*, in Equation 1). Note that it is possible for two individuals to have a profile shape quite similar to a modal profile depicted in Figure 1, even though the two individual profiles may be widely different in elevation. For example, a psychiatric patient and a normal subject may show a high degree of similarity to the neurotic modal profile, indicating respective high points on *Hs*, *D*, and *Hy*. However, these two individuals may be differentiated at a second stage when considering elevation. One would expect the psychiatric patient to show more severe psychopathology and thus to have high points close to or exceeding a *T* score of 70.

Also depicted in Figures 1, 2, and 3 is the mean MMPI profile for a reference group taken from Lanyon (1968). These reference group profiles provide "real world" exemplars of the three ideal types. The somatization reaction profile plotted in Figure 1 represents a group of 39 white veterans from the psychiatry service of the Minnesota Veterans Administration Hospital (Rosen, 1958). Only "pure" cases were selected for this diagnostic category. The MMPI profile for this group has a marked similarity in shape ($r = .93$) to the neurotic modal profile, although the somatization reaction profile is higher in elevation. Similarly, Figure 2 presents the MMPI profile of 100 white male veterans from the psychiatry service of the Minnesota Veterans Administration Hospital who had been diagnosed as paranoid schizophrenics (Rosen, 1958). This profile substantially resembles the shape ($r = .92$) of the psychotic modal profile. However, the paranoid schizophrenics' profile is higher in elevation. Finally, Figure 3 presents a male narcotic addict's profile based on adult addicts treated at the Patton (California) State Hospital (Olson, 1964). This reference group profile closely resembles the shape ($r = .82$) of the sociopathic modal profile and is slightly higher in profile elevation.

Classification results for selected group profiles from Lanyon's (1968) compendium are given in Table 3.¹ The three modal profiles accounted for 68.79% of the variance due to pro-

¹ Data for the complete set of 233 groups are available from the authors.

Note. The elevation parameters M_i are the mean of the 13 clinical scale T scores, scatter parameters S_i are the profile standard deviation, and shape parameters A_i are the correlation between a code type and respective modal profile of Table 1.

file shape among the 233 Lanyon (1968) groups. Furthermore, using an entrance criterion of a highest loading above .50, 84.55% of the 233 groups can be classified as salient on a specific modal profile (cf. Skinner et al., 1976). These findings provide encouraging support for the generalizability of the three MMPI modal profiles among diverse deviant and normal samples. Note that classification data analogous to those contained in Table 3 can be readily com-

puted (see computational summary below) for any sample of patients with scores on the 13 MMPI clinical scales.

Given the classification results exemplified by Table 3, graphic displays can be constructed to facilitate interpretation of the data. That is, the elevation (M_i) and shape (A_i) parameters provide coordinates on orthogonal axes (Skinner, 1977, in press; Skinner, Note 1). For example, Figure 4 plots elevation by shape for

Note. The number in parentheses after the group name refers to the figure number in Lanyon's (1968) book.

the psychotic modal profile. The horizontal axis represents the degree to which each code type from Table 2 (or any new MMPI profile) matches the *shape* of Modal Profile II. The vertical axis depicts the degree of profile *elevation*. Along with selected code types, two schizo-

phrenic group profiles (Lanyon, 1968) are plotted in Figure 4. Although the two profiles substantially resemble the shape of Modal Profile II, the schizophrenic 15- to 29-year-old group was lower in profile elevation than the paranoid schizophrenic group. Figure 5, on the

Figure 4. Plot of shape versus elevation for the psychotic modal profile. (G denotes a Gilberstadt and Duker, 1965, code type, and M designates a Marks, Seeman, and Haller, 1974, code type.)

other hand, displays the degree to which selected code type and Lanyon (1968) group profiles resemble the shape of Modal Profile I (neurotic) versus Modal Profile II (psychotic). Both figures provide a convenient summary of the classification analysis.

Discussion

This new method of identifying an MMPI taxonomy can be readily used in applied settings. That is, given a patient's MMPI profile in *T*-score format, the computational steps for forming Equation 1 are quite straightforward:

1. Compute the patient's average over the 13 MMPI clinical scales *T* scores to yield the elevation parameter (M_i).
2. Compute the standard deviation of the 13 MMPI scales about this patient's average to give the scatter parameter (S_i).
3. Compute the correlation of the patient's profile with each of the three modal profiles (Table 1) to yield the three shape parameters (A_i).

The investigator should scan the three shape parameters to identify the highest weighting. If this value exceeds a minimum standard (e.g., .50), then a figure for the appropriate modal profile (cf. Figure 4) should be constructed. The position of this patient can be located, given the elevation and shape coordinates. If, for example, a patient's location is most proximal to code 1-3-2 from Gilberstadt and Duker (1965), then the clinician could interpret the body of information regarding code 1-3-2 with respect to this patient. Furthermore, a secondary (tertiary, etc.) classification is possible by examining the location of this patient relative to other code types in the ordination space. Finally, one can interpret the theoretical and empirical data accumulated for the appropriate superordinate modal profile.

A technical issue concerns the degree of reliable differentiation among code types proposed by each system. Note that the three modal profiles of Table 1 explain (reproduce) 81.92% of the covariation among the 35 code types. That is, with three underlying "ideal type constructs," one is able to capture most of the common variance among the Gilberstadt and Duker (1965) and Marks et al. (1974) systems.

Figure 5. Plot of the neurotic (I) versus the psychotic (II) modal profile. (G denotes a Gilberstadt and Duker, 1965, code type, and M designates a Marks, Seeman, and Haller, 1974, code type.)

Certainly, one could question whether two code types within one system that are close together in the ordination space (e.g., Marks et al.'s, 1974, codes 2-8 and 8-6 of Figure 4) represent reliable differences. They should probably be collapsed into one code type.

From a theoretical perspective, it is hypothesized that the shape parameters yield indices of the patient's more enduring personality disposition (Lorr, 1966), whereas elevation and scatter reflect more temporary or situational factors influencing the degree of maladjustment (Carlson, 1972; Mori & Krane, 1973; Quertin, 1966). By examining the independent contribution of elevation, scatter, and shape components of profile similarity (Skinner, 1977, in press), one can integrate various aspects of the trait (core) and social-learning (situational) theory approaches to the study of personality (Bowers, 1973). For example, if pretreatment and posttreatment data are available, one could fit the MMPI modal profiles to each data set and then examine the temporal stability of the elevation, scatter, and shape parameters. One might hypothesize that patients will be classified in the same modal profile on each occasion when considering shape. However, a decrease in the elevation parameter could be predicted corresponding to

a reduction in symptom severity in response to a successful treatment program.

Although relatively homogeneous subgroups or clusters can be identified in the ordination space (cf. Figures 4 and 5), the current approach is essentially a dimensional model. The level of differentiation implicit to the three superordinate modal profiles is similar to Goldberg's (1972) hierarchical classification (i.e., normal vs. deviant; neurotic vs. psychotic vs. sociopathic).

In conclusion, the three MMPI modal profiles form a typological model of psychopathology that is open to empirical evaluation. Hopefully, this model will guide further theoretical developments and empirical research in the study of psychopathology. Expanding the system to more than three modal profiles will require additional psychopathological groups using more differentiated and less highly correlated personality scales than those comprising the MMPI clinical scales. Furthermore, by building on the actuarial systems of Gilberstadt and Duker (1965) and Marks et al. (1974), the present model should provide a convenient and useful diagnostic basis for clinical decision making.

Multimodal Evaluation of Practice Interactions as Treatment for Social Isolation

W. Stephen Royce and Hal Arkowitz
University of Oregon

Socially isolated college students, 28 men and 26 women, who volunteered for a program to increase social comfort and activity in friendship interactions, were randomly assigned to a treatment involving 12 real-life practice interactions with other subjects, a treatment involving 12 practice interactions plus 9 hours of social skills training, a minimal treatment control condition, or a delayed treatment control condition. Outcome was evaluated by multiple criteria that included self-report, self-monitoring, peer rating, and behavioral measures. Results indicated no significant differences between the two treatment groups or between the two control groups. The two treatment groups showed substantial and significant improvements in contrast to each control group on measures of social anxiety and social activity. These gains were maintained at follow-up assessments 3 and 15 months posttreatment. It is argued that the practice interaction treatment may function as *in vivo* desensitization, thereby reducing social anxiety and leading to increased social activity.

Recently, there has been a considerable amount of research on the assessment and treatment of minimal dating problems (Arkowitz, 1977; Curran, 1977). Surveys have indicated that social anxiety and minimal dating are significant and pervasive concerns for many individuals (e.g., Bryant & Trower, 1974). Several behavioral treatment procedures have been developed and evaluated for these problems, such as social skills training procedures involving behavior rehearsal, modeling, coaching, and feedback (e.g., Twentyman & McFall, 1975); anxiety-reduction procedures such as systematic desensitization (e.g., Curran & Gilbert, 1975); and cognitive modification

procedures (e.g., Glass, Gottman, & Shmurak, 1976).

Despite the considerable interest in minimal dating and the apparent efficacy of these different procedures, there has been very little attention directed toward another significant social problem—*anxiety and isolation in same-sex friendship interactions*. Friends provide opportunities for social comparison and information regarding social norms. In addition, they provide opportunities for modeling and feedback, which can have considerable influence in shaping a variety of social behaviors. Friendship relationships can also provide emotional support and comfort in times of stress. Thus, the lack of friendship relationships can severely limit an individual's social and emotional growth.

This article is based on a doctoral dissertation by the first author under the direction of the second author. The authors wish to thank Edward Lichtenstein, Susan Gilmore, Sheldon Cohen, and Dorothy Largay for their assistance in planning and executing this study. Gratitude is extended also to Kay Patterson, John Stanwood, Michael Shewin, and Jeff Lothman for their assistance in data collection and analysis.

Hal Arkowitz is now at the University of Arizona.

Requests for reprints should be sent to W. Stephen Royce, who is now at the Department of Psychology and Social Sciences, University of Portland, 5000 North Willamette Boulevard, Portland, Oregon 97203.

In the present study, a treatment approach that has been effective for minimal dating was applied to the problem of social anxiety and isolation in same-sex friendship interactions. The approach is based on real-life practice and involves repeated exposures to moderately anxiety-arousing social situations in the natural environment (Arkowitz, Christensen, & Royce, 1975). The procedure for minimal dating has involved providing subjects with a series of

six "practice dates," each with a different randomly selected partner who was also a volunteer for the program. Research has demonstrated that the procedure of practice dating leads to significant decreases in social anxiety and increases in posttreatment dating activity with new partners whom the subjects met on their own (Christensen & Arkowitz, 1974; Christensen, Arkowitz, & Anderson, 1975; Kramer, 1975). The effectiveness of the procedure appears to be due primarily to anxiety reduction (Christensen et al., 1975). An advantage of the practice dating procedure is that it can be administered on a large scale basis by someone trained only in clerical skills. In addition, since the treatment takes place in naturalistic situations, there is minimal concern about generalization from the therapy situation to the subjects' natural environments.

The procedure evaluated in the present study consisted of randomly pairing members of the same sex for a series of such "dates." This practice interaction group was compared to a second treatment group that received an identical series of practice interactions plus social skills training. (To the extent that subjects are characterized by inadequate social skills, the anxiety reduction effected through the practice interactions may not be sufficient for durable change to occur.) A minimal treatment group was used to control for attention and expectancy factors (Paul, 1969). A delayed treatment control group and a no-treatment group (to serve as a control for follow-up) completed the design. It was hypothesized that the two treatment groups would show significant improvements on multiple criteria of social skills, anxiety, and activity, relative to each of the control groups. It was also hypothesized that the practice interactions plus social skills training group would be superior to the group that received practice interactions only.

Method

Subjects

All subjects were college students, 18-23 years of age, who had telephones at their residences. The target population for the study was the most socially distressed 15% of approximately 1,000 students who completed a social survey questionnaire distributed in a number

of large classes. Since norms for social activity and anxiety in friendship interactions were not available, this selection criterion assured that subjects were considerably distressed and inactive.¹ Twenty-eight subjects were male, and 26 were female. Their mean age was 19.8 years, and 8% described themselves as married or cohabiting, 18% as engaged or steadily dating one person, and 74% as single.

Experimental Design

Subjects were randomly assigned among the two treatment groups and two control groups. Initial group sizes were 13 subjects in the practice-only group, 14 in the practice plus skill training group, 11 in the minimal treatment control group, and 16 in the delayed treatment control group. There was no mixing of sexes at any point in the study; males and females were treated separately but identically. Assessment was conducted pretreatment, posttreatment, 3 months posttreatment, and 15 months posttreatment. Because the delayed treatment control group was not available for control purposes at follow-up (they had received treatment by then), a follow-up control group was separately recruited.

Assessment

Self-report questionnaires. Two questionnaires were administered to all groups pretreatment, posttreatment, and at follow-up. The Social Avoidance and Distress Scale (Watson & Friend, 1969) is a 28-item social anxiety scale that has been demonstrated to possess good reliability and validity (Arkowitz, Lichtenstein, McGovern, & Hines, 1975; Watson & Friend, 1969). The self-report questionnaire consisted of free-response questions of retrospective frequency and range of same-sex social interactions and of dates and 7-point rating scales of same-sex social anxiety and social skills.

Self-monitoring measures. Subjects were asked to record their social interactions over a period of a week in a social interaction diary, which they carried with them. These diaries yielded a measure of the frequency and range (number of different people) of same-sex and opposite-sex interactions in a 1-week period. Interactions that did not progress beyond a mere greeting were not recorded. This procedure had been used by Christensen et al. (1975) in their practice dating study. The diary was administered pretreatment and posttreatment to all subjects except those in the follow-up control group.

Peer ratings. A peer questionnaire was sent to two male and two female acquaintances of each subject. The questionnaire yielded same-sex and opposite-sex social competence scores, based on ratings of social anxiety, social skills, and social activity. Because there

¹ For a more detailed description of the selection criteria used in this study, as well as a discussion of some general issues regarding selection criteria in studies of this type, see Royce and Arkowitz (1977).

seemed likely to be a substantial lag between changes in subjects' behavior and their peers' perceptions of these changes, this questionnaire was administered to all groups pretreatment and at the 3-month follow-up only.

Behavioral performance task. Subjects were brought into the laboratory where they engaged in a 10-min conversation with another subject. Four measures for each subject were taken from the audio recordings of the interactions: total talk time, number of silences longer than 10 sec, and ratings of social skill and social anxiety. These ratings were made by a corps of 22 untrained undergraduates. Five or six raters of the same sex as the subject independently rated each interaction. The means of these ratings yielded each subject's scores. This procedure, rather than the more usual one of training a small number of raters to a high degree of interrater agreement, was used to avoid the problem of relying solely on interrater agreement as the criterion of rating accuracy (Johnson & Bolstad, 1973; Lipinski & Nelson, 1974). The procedure yielded instead a representative peer opinion as to what constituted levels of social anxiety and skill. These measures were collected pretreatment and posttreatment from all subjects except those in the follow-up control group.

Process ratings. After each practice interaction, subjects completed ratings of themselves and their partners on 7-point scales of social anxiety and social skill.

Treatment

Practice only. Subjects were matched for 12 practice interactions, 2 per week, with a different same-sex partner each week. Matching was completely random. Each subject was sent the name and telephone number of his or her partner at the beginning of each week. Both interactions with that partner had to occur within a week, but decisions about all other details (initiation, time, place, length, etc.) were left up to the subjects.

Practice plus skill training. Subjects in this group participated in a series of 12 practice interactions as the practice-only subjects did. In addition, these subjects attended six weekly group social skills training sessions. Each group meeting lasted 1.5 hours. Except for the initial meeting of each group, the first 30 minutes of each session were devoted to feedback given to each subject by her or his partner from the previous week's interactions. The remaining hour was devoted to social skills training. Each week, subjects received a chapter from a social interaction training manual, based on similar manuals developed by McGovern (1972) and by Watkins (1972). Each chapter provided information about a particular topic in the realm of socially effective behavior and ended with a number of paper-and-pencil exercises to be completed by the subject during the week. Each group session was devoted to skills training in the area defined by the week's reading and exercises. Modeling and behavior rehearsal were the primary techniques used.

Minimal treatment control. Subjects in this group participated in six weekly group counseling sessions,

similar in format to the groups attended by the practice plus skill training subjects. These control subjects received the same readings and exercises as the practice plus skill training subjects, but group meetings consisted only of discussion and verbal counseling. These subjects received no practice interactions.

Delayed treatment control. Subjects in this group were telephoned and informed that the limitations of the program staff and facilities and the large number of volunteers for the program necessitated a delay in treatment for them. They were told that they would be able to participate in the program during the following academic quarter.

Follow-up control. Since the delayed treatment control subjects received treatment prior to any follow-up assessment, a separate group of subjects was recruited to serve as a no treatment control for follow-up. This group consisted of 13 male and 12 female students who had scored among the most distressed 15% on the screening questionnaire passed out in classes and who met the other screening criteria but who had not been contacted about participating in the treatment study. Data from these subjects were obtained only on the Social Avoidance and Distress Scale, the self-report questionnaire, and the peer questionnaire.

Procedure

Prospective subjects came in for a screening interview and to receive written and verbal explanations of the program. Interested and eligible subjects then signed a contract and consent form and paid a \$2 fee to cover expenses plus a refundable \$10 security deposit. During the third week of the winter academic quarter, pretreatment assessment was done. Treatment was given through the remainder of the winter quarter. Posttreatment assessment was administered during the second week of spring quarter, and subjects' \$10 deposits were then refunded. Delayed treatment control subjects were treated with practice plus skill training during spring quarter. Three months after treatment all subjects except those in the delayed treatment control group were paid \$1 to complete the follow-up questionnaires. The peer questionnaires were mailed again at that time. Fifteen months after treatment, practice-only and practice plus skill training subjects were again contacted and were asked to complete the follow-up questionnaires.

Results

All subjects completed the program, including posttreatment assessment, except for one practice-only subject, one practice plus skill training subject, and three delayed treatment control subjects. At the 3-month follow-up, there was an additional loss of two practice-only subjects, two practice plus skill training subjects, one minimal treatment control subject, and three follow-up control subjects. These losses were due to subjects'

lack of interest in further participation in the program.

One-way analyses of variance of pretreatment scores showed no significant differences among groups. In addition, the follow-up control group was compared to all other groups combined, and no significant differences were found.

Analysis of all data (except the process ratings and the 15-month follow-up data) was by analysis of covariance, with the pretreatment scores for each measure serving as the single covariate for each analysis. Since two-way (Sex of Subjects \times Treatment) analyses showed no significant sex or Sex \times Treatment interaction effects, sexes were combined and

one-way analyses were used. Consistent with the hypotheses stated earlier, analyses were by means of specific planned contrasts rather than by omnibus tests across all groups. Contrasts of practice only versus practice plus skill training showed no significant differences on any of the measures. Thus, there was no support for the hypothesis that social skills training would enhance the effects of the practice interactions procedure. Contrasts of minimal treatment control versus delayed treatment control versus follow-up control showed no consistent significant differences—Only 1 of the 24 contrasts reached the .05 level of significance. Detailed results are therefore reported only for the planned contrasts

Table 1

Means on Selected Outcome Measures for All Groups Pretreatment, Posttreatment, and at 3-Month Follow-up

Measure	Treatment group				
	P+	PO	MTC	DTC	FC
Social Avoidance and Distress Scale					
Pretreatment	13.7	14.8	13.1	13.6	10.0
Posttreatment	8.6	8.6	10.8	11.3	9.1
3-month follow-up	7.9	8.3	10.9		9.2
Social interaction diary					
No. same-sex interactions					
Pretreatment	24.8	20.7	41.8	33.5	
Posttreatment	42.2	39.8	42.1	34.4	
Range of same-sex interactions					
Pretreatment	13.8	14.1	16.5	19.7	
Posttreatment	20.4	23.5	16.5	14.6	
Peer questionnaire same-sex ratings					
Pretreatment	4.2	4.5	4.4	4.4	4.7

of the practice-only and the practice plus skill training groups combined versus each control group.

Outcome Measures

Table 1 presents the means on selected outcome measures for all groups pretreatment, posttreatment, and at the 3-month follow-up.

Social Avoidance and Distress Scale. At posttreatment, the combined practice groups had improved significantly on this measure in contrast to each of the three control groups: $t(35) = -2.01$, $p < .05$, for the contrast with the minimal treatment control group; $t(37) = -2.26$, $p < .05$, for the delayed treatment control group; and $t(49) = -3.12$, $p < .01$, for the follow-up control group. At the 3-month follow-up, the practice groups continued to improve relative to the minimal treatment control group, $t(30) = -1.98$, $p < .05$, and the follow-up control group, $t(42) = -2.49$, $p < .01$. Thus, the treatment groups showed clear superiority on this measure over the control groups both immediately posttreatment and 3 months posttreatment.

Self-report questionnaire. Responses to the questions about social interaction frequency and range, and number of dates, showed no significant improvements for the combined practice groups when compared to the control groups. On ratings of social anxiety, the combined practice groups improved significantly in contrast to each of the three control groups: $t(34) = -2.50$, $p < .01$, for the contrast with the minimal treatment control group; $t(33) = -2.19$, $p < .05$, for the delayed treatment control group; and $t(48) = -3.16$, $p < .01$, for the follow-up control group. At the 3-month follow-up, these contrasts were maintained for the minimal treatment control group, $t(31) = -3.83$, $p < .01$, and for the follow-up control group, $t(41) = -3.46$, $p < .01$. On ratings of social skill, the combined practice groups improved significantly only in contrast to the minimal treatment control group, $t(34) = 2.29$, $p < .05$, and the follow-up control group, $t(48) = 2.35$, $p < .05$. Only the latter contrast was maintained at the 3-month follow-up, $t(41) = 2.59$, $p < .01$. There was, then, substantial and consistent improvement

on self-rated social anxiety for the treatment groups and minimal improvement on self-rated social skill.

Social interaction diary. For both frequency and range of same-sex social interactions, the combined practice groups improved significantly in comparison to the minimal treatment control group, $t(34) = 2.64$, $p < .01$, for frequency, and $t(34) = 1.77$, $p < .05$, for range, and the delayed treatment control group, $t(33) = 2.49$, $p < .01$, for frequency, and $t(33) = 2.64$, $p < .01$ for range. There were no significant contrasts for opposite-sex interactions. It should be noted that for each of the practice groups, less than 2% of subjects' posttreatment interactions were with other subjects. Thus, these substantial increases in social activity were not due merely to subjects' interactions with people they met in the program.

Peer questionnaire. On the same-sex peer rating scale, the combined practice groups improved significantly in contrast to the follow-up control group, $t(45) = 3.56$, $p < .01$. The contrast with the minimal treatment control group was in the predicted direction and approached statistical significance, $t(28) = 1.34$, $p < .10$. Analysis of the individual items on this scale showed that these results were due primarily to changes in ratings of social activity, somewhat to changes in ratings of social anxiety, and not at all to ratings of social skill. There were no significant contrasts for the opposite-sex scale.

Behavioral performance task. None of the four measures taken from the audio recordings of these interactions showed significant contrasts.

Process Ratings

Matched sample t tests were used to compare practice subjects' process ratings from the first 3 weeks of treatment with ratings made during the last 3 weeks. Subjects' ratings of their own anxiety showed a significant decrease over time, $t(17) = 2.33$, $p < .02$. Subjects' ratings of their own skill and of their partners' anxiety and skill also changed in the predicted directions but did not reach statistical significance.

15-month Follow-up

Questionnaires were returned by 19 of the 27 subjects in the two practice interaction groups. Matched-sample *t* tests computed on the pretreatment to 15-month follow-up data revealed that improvements noted at post-treatment and at the 3-month follow-up had been maintained. The mean score on the Social Avoidance and Distress Scale decreased to 7.2, $t(18) = -3.95$, $p < .01$; self-reported range of social interactions with friends increased to a mean of 13.6, $t(18) = 2.34$, $p < .02$; and self-rated same-sex social anxiety decreased to 3.0, $t(18) = -2.55$, $p < .01$. There were no significant effects for the other self-report items.

Discussion

The results indicate that the practice interaction procedure was an effective treatment for socially isolated college students. On multiple outcome measures of social anxiety and social activity, the practice interaction groups improved significantly in contrast to the control groups, and these gains were maintained at 3-month and 15-month follow-ups. The practice interaction procedure worked equally well for men and women. Data from the social interaction diary indicate that the vast majority of posttreatment social interactions were between subjects and persons whom they had not met through the program. This suggests that substantial learning occurred as a result of the program, and that this learning generalized to social interactions with other persons.

Treatment did not have any significant effects on any of the behavioral or rating measures of social skill, with the exception of the self-report questionnaire rating. The lack of change on measures of social skill for the practice-only group is consistent with findings from practice dating studies, which have also found no changes in social skill (e.g., Christensen et al., 1975). A surprising finding was that the addition of social skills training did not lead to any improvements on measures of social skill. Studies with minimal daters have found significant increases in social skills ratings as a result of skill training procedures

very similar to the ones used in the present study (Curran, 1977). Although unlikely, it is possible that the social skills training procedure was not a good one. Or, it may be that the measures of social skills were not sensitive to changes that did occur. However, a third possibility is that subjects were not deficient in social skills to begin with. If this were the case, then one would not expect any marked improvements in subjects' social skills, even with a viable social skills training program. It may be that the majority of subjects were characterized by excessive anxiety but adequate social skills. Several studies with minimal daters have supported this view (e.g., Clark & Arkowitz, 1975; Glasgow & Arkowitz, 1975). It may be that the same is true for individuals who are socially isolated with respect to friendship interactions. If this hypothesis were correct, it would also account for the finding that social skills training did not enhance the effects of the practice interaction procedure.

A most interesting question at this point concerns the mechanism by which the practice interaction procedure works. It may be that by "forcing" subjects to be socially active, they are exposed to the natural reinforcing properties of social activity, which maintains an increased rate of social behavior. In a similar manner, the subjects' social activity in the program may lead them to change their self-perceptions and labels of being shy and socially awkward. However, the explanation that seems most tenable at this point is that the practice interaction procedure functions as a means of *in vivo* desensitization, in which repeated exposure to moderately anxiety-arousing situations serves to reduce social anxiety and avoidance. Results of the present study give some support to this hypothesis: The process ratings demonstrated that self-rated social anxiety decreased from the first 3 weeks of practice interactions to the second 3 weeks, whereas skill ratings did not change. Christensen et al. (1975) found similar results. There is now a large and growing body of literature that demonstrates the effectiveness of *in vivo* exposure as a means of anxiety reduction. Marks (1975) reviewed over 300 studies of behavioral approaches to anxiety reduction and concluded that "real-life exposure is the

most powerful therapeutic factor so far identified" (p. 93).

Other questions also remain concerning this procedure as treatment for social isolation. Although the procedure has been found to be an effective treatment for college students' social inhibitions, these results may not generalize to other populations. The subjects in this study were student volunteers, not real clients. Even though these subjects were screened stringently to approximate a clinical population and to minimize the analogue nature of the study, a true clinical population may differ in important ways from the sample in this study. The procedure may not work with more severely distressed clients or with those less intelligent and less verbal than college students. Such individuals may also need specific social skills training.

The present study assessed the outcome of treatment of 121 mental health center clients using therapist and independent global improvement ratings and independent ratings of notes in case records based on a client-specific goal-oriented outcome technique (Goal Attainment Scaling; GAS). Telephone follow-up of 50 clients provided a second GAS assessment, client global improvement ratings, and three consumer satisfaction ratings. The findings indicated that (a) independently determined GAS scores and therapist and independent global ratings converged significantly, (b) the GAS procedure provided some increase in accuracy as well as an increase in specificity of outcome, and (c) client global ratings may reflect satisfaction with treatment rather than outcome. In view of the intercorrelations among measures and the relationship between GAS scores determined from case records and telephone interviews, case records may provide for accurate assessment of client problems and treatment success.

The measurement of treatment effectiveness in the applied setting is subject to many constraints (Twain, 1975). Clinicians often resist the "invasion" of accountability into their professional activities because they fear that their individual efforts are not effective, resent the time spent in evaluation that could be used for therapy, or believe that the clinical process is not quantifiable (Ellsworth, 1975). A level of evaluation beyond simple program monitoring may also require shifting resources from clinical activities to research, a source of both clinical and administrative resistance. Furthermore, considerations such as objectivity about the program being evaluated, level of competency of the evaluators, and potential usefulness of the evaluation results often argue in favor of external rather than internal evaluation (Weiss, 1972). External evaluation,

however, may increase costs and further increase resistance.

Methodological considerations also make treatment outcome research difficult (Bergin, 1971). Though Bergin and Suinn (1975) and Malan (1973) have concluded that the evidence for effectiveness of psychotherapy is relatively strong, there is great concern with the adequacy of the measurement of that effectiveness (Fiske et al., 1970; Garfield, Prager, & Bergin, 1971; Luborsky, Chandler, Auerbach, Cohen, & Bachrach, 1971; Strupp & Bloxom, 1975). Indeed, the primary focus of discussion in psychotherapy research has been the criterion of outcome measurement. The most frequently used measure has been the therapist rating of client global improvement (Luborsky et al., 1971), which seems to be the only criterion that shows consistent correlations with other measures of outcome (Cartwright, Kirtner, & Fiske, 1963; Fiske, Cartwright, & Kirtner, 1964; Strupp & Bloxom, 1975). However, this criterion tends to reflect a more positive view of outcome than specific change measures (Garfield et al., 1971), and it is certainly not

oriented toward differentiating areas in which change occurred (Cartwright, 1975). Other measures are subject to similar concerns for validity and utility and have prompted suggestions that multiple measures be used (Waskow & Parloff, 1975).

The aforementioned constraints on evaluation in the applied setting and concerns for treatment outcome measurement influenced the design of the present study. Based on suggestions by Fiske et al. (1970) and Luborsky et al. (1971) that criterion measures should be oriented toward the type of change or goals each patient needs or desires, the present study incorporated the client-specific, goal-oriented technique developed by Kiresuk and Sherman (1968). This technique (Goal Attainment Scaling; GAS) has been extensively used in various mental health, drug, criminal justice, rehabilitation, and education settings (cf. Garwick & Brintnall, 1974). In the present application, goals were established and attainment was measured retrospectively by independent raters who reviewed case records of former clients. This retrospective approach avoided potential resistance by eliminating therapist involvement in the evaluation, provided independent external evaluation, and represented a test of the utility of an innovative approach to studying treatment effectiveness at relatively low cost. Global improvement ratings by therapists and raters provided an indication of the correspondence between these more typical criteria and this novel outcome measurement approach (GAS).

In addition to outcome assessment at termination, a telephone follow-up of a sample of clients provided a second GAS score and client global improvement ratings to explore their utility as convergent outcome criteria. Clients were also asked three questions to see if their satisfaction with services might reflect improvement during treatment. Altogether, the present study used eight outcome measures in three content areas: GAS, global improvement, and consumer satisfaction.

Method

Setting

The present investigation was conducted at Granite Community Mental Health Center. The therapeutic orientation of the center is eclectic with a primarily

dynamic focus, and all traditional therapist categories are represented.

Observations

Terminated client case records ($N = 179$) were drawn in a 10% random sample from about 1,700 files that met two criteria: (a) Treatment was received from January 1, 1970, to June 30, 1975; and (b) the clients had completed at least 10 outpatient sessions, 8 partial hospitalization days, or 5 inpatient days. The second criterion was intended to insure that case records contained enough information to permit assessment of problems and outcomes using GAS. Despite this precaution, 58 of the case records were not amenable to outcome assessment for at least one of three reasons: inadequate intake notes (53%), inadequate progress notes (72%), and/or inadequate termination notes (91%).

Of the 121 measurable cases, 84 received outpatient treatment (mean of 26.6 sessions), 29 received partial treatment (24.5 days), and 8 received inpatient treatment (26.4 days). Fifty-three percent of the clients received primarily individual therapy, and 47% received primarily group or family therapy. (Only the record of the sampled family member was evaluated.) Four clients were treated by psychiatrists, 25 by psychologists, 59 by social workers or nurses, and 33 by paraprofessional therapists. Forty-eight percent of the clients were male. The average was 33.4 years (range = 11–70 years), and average formal education was 11.7 years. Thirty-four percent of the sample were single, 42% were married, and 24% were separated or divorced. Average family income was \$7,200 yearly, and average client family size was 3.96. Fifty percent of the clients had received some prior mental health treatment. The 188 problem areas identified for the 121 cases with measurable outcome were classified into 10 general categories: parent-child interactions (23.9%), depression (16.5%), marital problems (16.0%), other relationship problems (10.1%), self-understanding (9.0%), school problems (6.9%), anxiety (4.2%), agency referrals (3.7%), work problems (3.2%), and other problems (6.5%).

A comparison between clients for whom outcome could be assessed ($n = 121$) and for whom outcome could not be assessed ($n = 58$) revealed no significant differences in duration or type of therapy (individual or group or family), category of therapist, or client demographic characteristics. Fifty of the 121 clients whose records were measurable were reached for telephone follow-up. Of the 71 who could not be interviewed, 33.8% were not reached by a cutoff of three calls (which included the use of directory assistance to pursue changed numbers), 50.7% had moved or changed numbers that could not be traced, and 15.5% had no telephone listing. Again, there were no apparent treatment or client differences between those interviewed and those not interviewed.

Procedure

Two advanced graduate students in clinical psychology who had no affiliation with the Granite Com-

munity Mental Health Center contracted to conduct the retrospective outcome study and telephone follow-up. Both raters were trained in assessment and had some experience with GAS through designing evaluation programs and training staff in two applications of that technique.

Goal Attainment Scaling is a client-specific assessment and outcome technique developed by Kiresuk and Sherman (1968) to measure success in meeting treatment goals. It is used to (a) select one or more client problems during initial assessment, (b) establish possible outcome levels for each problem, and (c) compare actual outcome with established levels. Selected problems are each translated into verbal descriptions of possible outcome levels based on a common 5-point scale, which ranges from the least favorable treatment outcome thought possible (scale value = -2) to the most favorable outcome thought possible (+2). The expected outcome of treatment (scale value = 0) is based on clinical judgment about the most likely outcome for the individual client's particular problem. A goal attainment score with an expected value of 50 and an expected standard deviation of 10 can be computed for each client by combining scale outcome levels using a formula developed by Kiresuk and Sherman. A score of 50 indicates average expected treatment outcome, and a score of more than 50 indicates more than expected outcome. Computation of a single score for each client allows for comparisons of outcome between clients or programs.

As originally designed, the GAS technique requires therapist-client interviews for scale construction and outcome assessment, which can take up to 2 hours of client and therapist time. The retrospective nature of the present approach allowed scale construction and outcome measurement using only the closed case record. Scales were constructed from intake notes, and outcome was assessed from progress and termination notes. GAS scores were computed for each client's status at intake and termination, thus allowing measurement of changes during treatment. All problems in the intake notes that could be made into goals were scaled. Since their relative importance could not readily be determined, all goals were considered equally important for the purpose of computing GAS scores (cf. Kiresuk & Sherman, 1968).

Additional outcome measures included global ratings made by therapists, raters, and clients using 6-point scales (where 1 = considerably worse, 3 = unchanged, and 6 = considerably improved). Therapist global ratings were routinely made at termination and were available in the case records. Rater global ratings were made at the time termination GAS scales were assessed. Client global ratings were requested during telephone follow-up.

Telephone follow-up was conducted at an average of 2 years after treatment termination. The raters who interviewed the clients were unaware of clients' status at follow-up. Raters asked clients to indicate their status on each GAS by first reading them the termination level. (Clients were *not* told that this was the status recorded by their therapist at termination.) If clients described themselves as better or worse, the raters read the next scale level in the indicated direction.

They continued until the client said the appropriate level was reached, or the end of the scale was reached, whichever came first. Those levels for each client were then used to compute the follow-up GAS score.

Clients were next asked to rate the extent to which they felt they had improved since they first came to the Granite Community Mental Health Center for treatment using the global scale. Three additional questions were asked of each client to assess relationships between satisfaction with services and treatment outcome. Clients were asked to rate whether they would return to the center if they needed help in the future and whether they would recommend the center to others needing help on a 5-point scale (where 1 = definitely no, 3 = maybe, and 5 = definitely yes). Actual recommendation to others was scored dichotomously as the third measure.

Reliability

With any task involving rating, reliability of the ratings is an important issue. Prior to conducting the present study, the two raters spent approximately 8 hours each in training to apply the GAS technique to the case records. They determined subjective criteria (based on the amount and quality of information in the record) for deciding whether outcome was measurable, discussed goals and scale points for several cases, and independently developed and then discussed goal attainment scales for 12 records. Reliability assessment was conducted independently by the two raters on 27 cases of the 179 reviewed (13 initially reviewed by one rater and 14 by the other). There was complete agreement that 7 of the case records were not amenable to scale construction. For the 20 case records allowing outcome assessment, correlations of .94 and .93 were obtained between raters on termination GAS scores and global improvement ratings, respectively. These 20 case records allowed identification of 36 problem areas, for which there was 86% agreement between raters on the scale headings used to describe problems. The average termination outcome level for 121 clients was 48.86, with a standard deviation of 9.77. The similarity between the findings of the present study and the expected values of 50 and 10 suggest that the raters were correctly using the GAS technique.

Cost

One intent of the present study was to provide a large amount of outcome data at relatively low cost. The retrospective outcome portion of the study cost \$1,017 in direct rater time and indirect staff support at a cost per case reviewed of \$5.68. Excluding training and support time, the average time spent reviewing each of the 179 cases was 21 minutes. This compares very favorably with past efforts at outcome assessment at the Granite Community Mental Health Center. The telephone follow-up cost \$6.72 per case for the 50 clients who could be reached. The center administration has concluded that the benefits of the present study fully justify the cost in money and time that might otherwise have been devoted to clinical efforts.

Table 1
Correlation Matrix of Outcome Measures

Measure	1	2	3	4	5	6	7	8
1. Termination GAS score	9.77							
2. Rater global improvement	.80***	1.05						
3. Therapist global improvement	.52***	.45***	.90					
4. Follow-up GAS score	.40**	.36**	.18	13.96				
5. Client global improvement	-.08	-.03	-.14	.49***	1.12			
6. Would client return?	.12	.15	-.02	.27	.51***	1.12		
7. Would client recommend others?	.08	.15	-.06	.26	.50***	.74***	1.02	
8. Did client recommend others?	.00	.00	.08	.11	.50***	.28*	.27	.46

Note. Values in the diagonal are standard deviations. The measures are based on degrees of freedom of 119 for 1 and 2, 116 for 3, and 48 for 4-8. Significance tests are two-tailed. All correlations involving Measure 8 are point biserial. GAS = Goal Attainment Scaling.

* $p < .05$.

** $p < .01$.

*** $p < .001$.

Results

Both intercorrelations among outcome measures and the correspondence in magnitude of similar measures (e.g., global improvement ratings) obtained from different sources (e.g., therapists, raters, and clients) were of importance to the present study. The intercorrelations among measures are presented in Table 1. Notably, convergence among the major outcome measures was significant. Rater-determined termination GAS scores, $r(116) = .52$, $p < .001$, and rater global improvement ratings, $r(116) = .45$, $p < .001$, were both significantly correlated with therapist global improvement ratings. Likewise, termination GAS scores, $r(48) = .40$, $p < .011$, and rater global ratings, $r(48) = .36$, $p < .01$, were significantly correlated with client follow-up GAS scores. Moreover, only 1 of the 50 clients contacted at follow-up reported that the problem areas discussed were not those that brought them to treatment. However, the relationship between therapist and global ratings and follow-up GAS scores was not significant. Thus, GAS scores derived independently from the case record appear to provide a somewhat better index of client functioning than therapist global ratings, especially when both termination and follow-up are considered. It is also of interest to note that termination GAS scores and rater global ratings were highly correlated, $r(119) = .80$,

$p < .001$, which suggests that raters used similar criteria with these measures.

Client global ratings correlated significantly with follow-up GAS scores, $r(48) = .49$, $p < .001$, but not with therapist or rater global ratings or with termination GAS scores. Yet, client global ratings were substantially correlated with all three consumer satisfaction ratings (i.e., whether the client would return for treatment, whether the client would recommend others, and whether the client did recommend others). In fact, measures obtained during follow-up tended to be internally consistent but (with the exception of follow-up GAS scores) were independent of other measures. That is, client global ratings and the three consumer satisfaction ratings tended to correlate significantly with each other but not with other outcome measures.

With respect to the magnitude of measurements, the change in average GAS scores from intake (38.84) to termination (48.86) was highly significant, correlated $t(119) = 11.02$, $p < .001$. This finding confirms the sensitivity of the GAS procedure for revealing changes and its accuracy in approximating the expected level of 50. In addition, the 50 clients in the follow-up sample had a mean termination score of 49.54 and a follow-up score of 51.85, which were not significantly different. Clients seemed to improve during therapy and to maintain that improvement after therapy.

The magnitude of global ratings provided an additional perspective for evaluating the GAS procedure. Although the mean ratings of raters (4.06) and therapists (4.39) both indicated moderate improvement at the end of treatment (i.e., ratings of 3 = "unchanged" and 6 = "considerably improved"), therapists' ratings were significantly higher, correlated $t(116) = 3.84, p < .005$. Since there was high agreement between rater global ratings and termination GAS scores, the difference in mean ratings between raters and therapists suggests that therapist global ratings overestimate improvement (cf. Garfield et al., 1971).

Discussion

The present study evaluated the application of GAS to client case records as a measure of treatment effectiveness and examined its correspondence to other measures of outcome. The most important findings were that GAS scores derived from case records by independent raters at the termination of treatment converged significantly with therapist ratings of global improvement and GAS scores obtained from client reports at follow-up. Also, a comparison of GAS levels at intake and termination, together with the scores derived at termination and follow-up, indicated that the GAS procedure is sensitive to changes produced by treatment and is accurate in predicting expected outcome. In fact, results suggested that the GAS procedure is more accurate in measuring outcome (cf. Garfield et al., 1971; Luborsky et al., 1971). An important question, however, is whether raters can assess client problems from the case record. The significant correlation between GAS scores determined from the case record and GAS scores determined from a client interview seems to mitigate this concern. Additionally, only 1 client of the 50 interviewed reported that the problem areas being discussed were not those that brought the client in for treatment. Thus, it seems that independent raters can accurately assess problems and outcome from the case record.

Although client global improvement ratings appear to have face validity (i.e., they should reflect the client's experience with treatment),

and sometimes correlate with other outcome measures (Cartwright, 1975), client global ratings in the present study were unrelated to rater or therapist global ratings or GAS scores determined from case records. On the other hand, client global ratings were strongly related to whether the client would return for treatment, would recommend the center to others, and had recommended the center to others. Perhaps, when questioned about improvements during treatment, client reports largely reflect satisfaction with services rather than gains made.

Finally, it can be noted that the GAS procedure used in this study circumvented many problems frequently encountered in therapy outcome evaluation (cf. Ellsworth, 1975; Twain, 1975; Weiss, 1972), and provided a large amount of data at relatively low cost (cf. Fiske et al., 1970). In addition, dissemination of the generally positive results of this study have reduced staff resistance to evaluation and prompted center plans for further investigation, thereby carrying the intent of evaluation to utilization within the program evaluated (cf. Davis & Salasin, 1975).

Comparison of Cardiovascular Biofeedback, Neuromuscular Biofeedback, and Meditation in the Treatment of Borderline Essential Hypertension

Richard S. Surwit
Department of Psychiatry
Harvard Medical School

David Shapiro
Department of Psychiatry
University of California, Los Angeles

Michael I. Good
Department of Psychiatry, Harvard Medical School

This study compared the separate effects of three procedures for the reduction of high blood pressure (BP) in three treatment groups of eight patients each with medically verified borderline hypertension: (a) Biofeedback for simultaneous reductions in systolic BP and heart rate was aimed directly at reductions in BP. (b) Biofeedback for reductions in integrated forearm and frontalis muscle electromyographic activity was aimed at general muscular relaxation. (c) Meditation relaxation based on the "relaxation response" procedure developed by Herbert Benson was aimed at total bodily and "mental" relaxation. Each patient was studied in two baseline sessions, eight training sessions, and a 6-week follow-up. Half of the sample returned for a 1-year follow-up. Analysis of variance of the three treatment groups over eight training sessions, 20 trials per session, revealed significant effects for trials within sessions. However, there were no significant main effects or interactions related to differences between the treatment conditions or to changes in BP over the course of training sessions. Although all groups showed moderate reductions in BP as compared to initial values, no technique could be seen to produce a reduction in pressure greater than that observed in the baseline sessions. BPs of patients reporting for the 1-year follow-up were not different from pretreatment baseline levels.

Essential hypertension has long been of interest to those concerned with behavioral factors in disease. The disorder occurs in about 10% of the population and is known to be affected by behavioral therapies (Shapiro, Mainardi, & Surwit, 1977). It remains unclear, however, as to which behavioral approaches

can add most substantially to treatment programs for the disorder. The main purpose of this study was to compare the efficacy of three behavioral methods in the reduction of blood pressure (BP) in patients with essential hypertension.

Of the many behavioral techniques that have been used for treatment of hypertension, none has attracted as much recent interest as biofeedback training for the control of BP. Shapiro, Tursky, Gershon, and Stern (1969) developed a constant cuff method to monitor relative changes in BP occurring at each beat of the heart and to provide information to subjects about these changes. With this method, small but reliable relative increases and decreases in either systolic or diastolic BP were obtained in normal subjects (Shapiro, Schwartz, & Tursky, 1972; Shapiro et al., 1969). Larger decreases in BP were found when feed-

This research was supported by National Institute of Mental Health Research Grants MH-26923 and MH-25104, Training Grant MH-06415, and Office of Naval Research Contract N00014-75-C-0150, NR201-152. back was provided for concomitant reductions in both heart rate (HR) and BP (Schwartz, 1972).

The constant cuff method of BP feedback was tested clinically in a series of case studies (Benson, Shapiro, Tursky, & Schwartz, 1971). Five patients with essential hypertension were trained to decrease systolic BP and showed reductions of 34, 29, 16, 16, and 17 mm of Hg after 33, 22, 34, 31, and 12 sessions of training, respectively. Using essentially the same procedure, Goldman, Kleinman, Snow, Bidus, and Korol (1975) reported decreases of 4% and 13% in systolic and diastolic BP, respectively, in seven patients with average baseline values of 167/109 mm of Hg. Kristt and Engel (1975) also reported success using the constant cuff feedback method. Patients suffering from essential hypertension and having a variety of cardiovascular complications were taught both to raise and to lower systolic BP and were able to achieve reductions in pressure averaging 10%-15% of their pretreatment baseline values.

Clinical data are less convincing for reductions in diastolic BP. Summarizing unpublished research, Miller (1975) noted that although some patients appeared capable of lowering diastolic BP, their pressure eventually drifted up over time. Negative results were also reported by Schwartz and Shapiro (1973). In this study, the constant cuff method was used to provide feedback for changes in diastolic BP. Only one out of seven patients studied showed a progressive reduction in diastolic BP; the others showed no change. However, Elder, Ruiz, Deabler, and Dillenkoffer (1973) reported using feedback and verbal praise to achieve a 20%-30% reduction in diastolic BP in patients who were not on antihypertensive medication. In addition, several studies previously discussed reported significant reductions in diastolic BP for patients who were actually trained to lower systolic pressure. Since morbidity has been shown to be related to elevations in systolic as well as in diastolic BP (Kannel, Gordon, & Schwartz, 1971), it may not be of great clinical consequence that diastolic pressure is more difficult to control with biofeedback methods.

Other biofeedback methods have been reported to be effective in the treatment of es-

sential hypertension. Moeller (1973) demonstrated that training patients to reduce frontalis electromyographic (EMG) activity through feedback training led to mean systolic and diastolic BP reductions of 13% in 36 essential hypertensive patients following 16 weeks of training. Patel (1973, 1975) used a combination of yoga and electrodermal (galvanic skin response; GSR) feedback to lower BP in hypertensive patients. In a well-controlled investigation, Patel and North (1975) randomly assigned 34 hypertensive patients to one of two treatment conditions. Patients in the first condition were initially taught relaxation with yoga and were then given GSR and EMG feedback in an effort to lower levels of autonomic and skeletal muscle activity. Patients in the second condition attended the same number of sessions (12), but they were told simply to recline on a lounge chair with no other specific instructions. Both groups showed reductions in BP, but the group that received yoga and biofeedback showed significantly greater reductions (from 168/100 to 141/88 mm of Hg) than the group that was simply instructed to rest (169/101 to 160/96 mm of Hg). Patients in the simple resting condition were then given 12 weeks of yoga plus biofeedback training and managed to lower their pressure to the level achieved by the first treatment group.

Another behavioral method reported to be effective in treating essential hypertension combines meditation and relaxation. Benson, Rosner, Marzetta, and Klemchuk (1974a, 1974b), using procedures derived from transcendental meditation (Maharishi Mahesh Yogi, 1966), demonstrated BP reductions in 22 untreated borderline and in 14 pharmacologically treated hypertensive patients. During the 6-week pretreatment baseline period, the borderline hypertension group showed an average systolic pressure of 147 mm of Hg and a diastolic pressure of 95 mm of Hg. During the 25 weeks of regular meditation relaxation, systolic BP was reduced by 8 mm of Hg and diastolic BP by 4 mm of Hg. The group being treated pharmacologically displayed an average systolic and diastolic BP of 146 mm of Hg and 92 mm of Hg, respectively, during a 5- to 6-week baseline period. The average reduction for this group during 20 weeks of regular meditation relaxation averaged 11 mm of Hg sys-

tolic and 5 mm of Hg diastolic. Using similar procedures, Stone and DeLeo (1974) recently compared meditation relaxation training to a no-treatment control in borderline hypertensive patients exhibiting pressures similar to those in the Benson et al. (1974a) study. Meditation relaxation was shown to produce small but significant pressure reductions (5–10 mm of Hg) as well as significant reductions in plasma dopamine-beta-hydroxylase activity and in furosemide-stimulated renin activity. On the basis of these data, Stone and DeLeo concluded that a reduction of peripheral adrenergic activity may be associated with the reduction of BP observed in the practice of meditation relaxation.

It seems clear that behavioral methods can produce reductions of BP. It is not clear, however, which methods are more effective than others and whether treatment effects are maintained consistently over time. Few follow-up data have been reported. Typically, various treatment approaches are combined, making it difficult to separate out critical variables and nonspecific or placebo effects. However, there is no easy solution to the problem of appropriate control procedures in evaluating behavioral therapies. The approach taken in this study was to compare several behavioral techniques. It was assumed that placebo effects would not differ across treatments, in that all treatments were "active" and could be expected to produce some change. Such a design allows a controlled comparison of efficacy and subject compliance, if subjects are randomly assigned to groups and treated over equal periods of time.

The present investigation compared three behavioral procedures in patients with essential hypertension: BP—biofeedback for reductions in BP and HR, EMG—biofeedback for simultaneous reductions in both frontalis and forearm muscle tension, and relax—a meditation relaxation practice. The rationale for the BP procedure was that BP biofeedback would facilitate direct control of reductions in BP and that simultaneous feedback for reduction in HR in this condition would serve to maximize the degree of BP reduction possible (Schwartz, 1972). The rationales for the other two conditions were also derived empirically. The EMG condition assumes that excessive

muscle activity is a critical factor in regulating high BP levels and that reduction in muscle activity facilitates pressure reductions.

By using the summed muscle activity of two muscle sites (frontalis and forearm) in the biofeedback procedure, it was assumed that total muscular relaxation would be facilitated. Further empirical support for muscle relaxation in essential hypertension has been reported by Shoemaker and Tasto (1975) with the use of a modified form of progressive relaxation. Moreover, it was further assumed that proprioceptive feedback of changes in muscle activity would aid in the development of learned control and maintenance of reduced muscle activity outside of the training situation. The relaxation procedure was assumed to maximize complete mental and physical relaxation. As hypothesized by Benson (1975), this method of relaxation produces a "hypometabolic state" that is presumed to represent a hypothalamic response that is antithetical to the "fight-flight" response and is consistent with a state of decreased sympathetic nervous system activity. According to Benson, the basic components of this form of relaxation are a mental device of mantra, a passive attitude, regular deep breathing, decreased muscle activity, and regular practice.

Follow-up evaluations of the treatment effects were made at 6 weeks and at 1 year after completion of the program.

Method

Subjects

Male and female volunteer subjects with hypertension were solicited through newspaper advertisements and physician referrals. After a preliminary telephone screening, potential subjects received (a) a letter of acknowledgement and an explanation of the study, (b) a confidential medical questionnaire focusing on history relevant to hypertension, and (c) a form requesting authorization for the volunteer's physician to release medical information. Subsequently, a description of the intent of the study was mailed to the volunteer's physician along with the authorized request for medical history including all available BP readings, summary of a physician's examination within the past year, and clinical laboratory data. Volunteers had to have their own physician agree to their participation in the study. The investigators did not assume the role of primary-care physicians.

Half of the volunteers considered for the study were taking antihypertensive or psychotropic medication,

Note. BP = blood pressure; L = lability; M = medication; EMG = electromyogram.

* Average prestudy blood pressure was measured in millimeters of mercury.

and the other half were not. The patients had a history of at least 1 year of labile or sustained systolic and/or diastolic hypertension (average systolic BP ≥ 140 , average diastolic BP ≥ 90). They were all less than 60 years old, and none had evident organic etiology for their hypertension, major complications related to the disease, or other serious illnesses (see Table 1).

Potential subjects whose histories met these criteria were then seen by one of the investigators for a detailed medical and psychosocial history, physical examination, and bilateral sitting and recumbent BP measurements. Subjects still meeting the criteria of the study were assigned to one of the three treatment groups. The groups were approximately matched for age, sex, current use or nonuse of relevant medication, type of blood pressure elevation (systolic and/or diastolic), and lability or stability of hypertension. BP was considered to be labile if the subject had a previous history of normal systolic and diastolic readings bracketed by elevated readings, with the lability being unrelated to medication effects. Subjects were requested to continue their current dietary and medication practices and to inform the investigators of any changes in their regimen during the study.

The BP and EMG groups were initially assigned nine members each, and the relax group, eight members. However, one subject in the BP group dropped out of the study, and one subject in the EMG group was excluded because of persistent tachycardia, leaving eight subjects in each group (Table 1).

Procedure

Subjects were scheduled to attend 10 sessions twice weekly for 5 weeks plus follow-up sessions approximately 6 weeks and 1 year after the 10th session. The first 2 sessions, 1 hour each, were used to obtain pre-treatment baseline measurements, and the remaining 8 1-1½ hours each, were experimental treatment sessions. To facilitate scheduling, approximately half of the subjects participated in either of two successive 5-week periods. In the baseline sessions, subjects were instructed to sit quietly and relax. The 3rd session marked the beginning of training. Subjects were read instruc-

tions appropriate for the experimental condition to which they were assigned. Instructions consisted of a brief reminder of the concept of psychophysiological BP reduction and a description of the general principle specific for the given treatment group. Instructions for the feedback or relaxation methods followed. The feedback groups were encouraged to use whatever mental strategy would result in the correct feedback. For the next 2 sessions, the instructions were paraphrased; and for the subsequent sessions, the subject was told: "I think you know the procedure by now. Are there any questions?"

Subjects were seated in a semirecumbent lounge chair in a wood-paneled sound-attenuated chamber. The following devices were connected to the subjects: a Biofeedback Systems, Inc., frontalis EMG headband consisting of three stainless-steel electrodes mounted in a rubber strap; two Beckman biopotential electrodes placed over the extensor for right forearm EMG; two silver-plate electrodes (right arm to left leg) and one silver-plate ground electrode on the right arm for the EKG; a respiration strain-gauge belt around the diaphragm; a crystal Korotkoff (K) sound microphone positioned over the left brachial artery and held in place by a BP cuff; and a Meditron electronic stethoscope affixed distal to the K sound microphone. During follow-up sessions, only the BP cuff and electronic stethoscope were attached. All recording was done in an adjacent instrument room. Two-way communication with the subject was maintained via an open intercom.

At the beginning of each session, with the subject alone in the training room, three BP measurements using the standard Riva-Rocci method were taken remotely by the experimenter in the adjoining instrument room. These readings were averaged to approximate the median systolic pressure, which was used as the initial constant cuff pressure setting. BP was then tracked continuously using the constant cuff method (Tursky, Shapiro, & Schwartz, 1972). All subjects were given 20 60-sec inflations (trials) separated by 30-sec rests. At the end of each trial, the cuff pressure was raised 2 mm of Hg if a subject showed K sounds following more than 75% of the heartbeats. Conversely, the cuff pressure was lowered by 2 mm of Hg for the next trial if K sounds followed less than 25% of the heartbeats. For each

group, sessions consisted of 20 60-sec trials, with the BP cuff inflated to median systolic pressure alternating with 30-sec intertrial intervals with the cuff deflated. In the BP and EMG training sessions, feedback was given only during the 20 60-sec trials. The constant cuff pressure on each trial constituted the basic BP data for all subjects.

For the BP group, BP and HR were measured, and changes in both were fed back using a pattern-feedback method (Schwartz, Shapiro, & Tursky, 1971). Briefly, BP was tracked as described previously. HR was tracked using a Lexington Instrument Company cardiographometer and a Grason-Stadler level detector. During the initial calibration period, median HR was determined. This is the HR at which half the interbeat intervals are faster and half are slower than that rate for a given series of heartbeats. The level detector was set at the median HR for the first trial and reset from trial to trial, depending on the number of interbeat intervals above and below that rate in the trial. The level was raised by 2 beats per minute (bpm) if 75% or more of the interbeat intervals were faster and lowered by 2 bpm if 25% or less of the intervals were faster than the median HR for the previous trial. In the feedback procedure, reductions of 2 bpm or more from the subject's median HR triggered the detector. During training, subjects in the BP group received feedback whenever HR dropped below the median level accompanied by a simultaneous reduction of BP (absence of K sound within 400 msec following the R wave). Feedback consisted of an auditory signal and visual feedback (cumulative digital meter). Subjects were instructed as follows:

During periods when the cuff is inflated, feedback in the form of a tone and increment on the meter will be provided whenever the equipment detects a decrease in your BP. If your BP goes up, or stays the same, no feedback will be given. Your job is to get as much feedback as possible (a high meter count) on each trial.

The EMG group heard a change in click signal frequency and observed the deflection of an analogue meter as average EMG activity varied during each 60-sec trial. The right forearm extensor and frontalis EMG readings were integrated by two Beckman EMG couplers. The combined average of these signals was used to drive a voltage-controlled oscillator, which produced auditory clicks directly proportional to integrated EMG activity. The integrated average of the two EMG signals also drove a large analogue meter placed directly in front of the subject. The task of the EMG group was to lower EMG activity using both auditory and visual feedback. Briefly, instructions were as follows:

Your task is to reduce your blood pressure by relaxing your muscles. During periods when the cuff is inflated, feedback for your muscle activity will be provided. As your muscle activity decreases, the meter in front of you will move to the left, and the clicking sound that you will hear will decrease in frequency. Conversely, if you tense your muscles, the meter will move toward the right, and the clicks

will increase in frequency. Your job is to decrease the click rate and keep the meter over to the left as much as possible.

The relax group was asked to meditate following the relaxation response method of Benson (1975) during the 20 trials of BP measurement. Briefly, instructions were as follows:

During the session, the BP cuff will be inflated from time to time for 1-minute periods. No other stimuli will be provided. When you are told to start, close your eyes and relax your muscles. Breathe through your nose. As you breathe out, say the word *one* silently to yourself. For example, breathe in...out, one, in...out, one, etc. Breathe easily and naturally. Continue until you are told to stop. Do not worry whether you are successful in achieving a deep level of relaxation. Maintain a passive attitude. If distracting thoughts occur, try to ignore them by not dwelling upon them and return to repeating one.

At the end of each session, subjects in each group were shown a cumulative graph of their total progress in lowering BP.

After the first training session, subjects were instructed to practice lowering BP as often as possible between sessions using whatever strategy they had arrived at during the laboratory sessions but without the aid of a sphygmomanometer or other instrumentation. Subjects were requested to record the nature and time of this practice, and the record sheets were collected before beginning each of the remaining seven training sessions. Generally subjects reported no significant changes during the course of training in their compliance with home practice. Nor were there any reported significant changes in medication during the course of training.

After the eighth training session, subjects were asked to return to the laboratory for a 6-week and a 1-year follow-up session. All subjects returned for the 6-week follow up, but only 13 returned for the 1-year follow-up (7 BP, 3 EMG, 3 relax). During both follow-up sessions, a BP cuff and an electronic stethoscope were attached to the left arm. The subjects were then left alone in the laboratory, and they were asked to practice the strategy for lowering pressure that they had learned during training. No feedback was provided for any subjects during these sessions.

Two female experimenters ran equal numbers of subjects in all three groups. Each subject was run by the same experimenter throughout the experiment.

Results

Pretreatment Baseline Data

To determine if the three treatment groups differed in average BP prior to the beginning of training, an analysis was made of five pretreatment pressures: (a) average BP obtained in the prior medical history, (b) average BP obtained

Figure 1. Mean blood pressure (measured in millimeters of mercury; mm Hg) collapsed over treatment groups over the course of the study. (For Follow-up II, $n = 13$, Med. = medical; Exp. = experimental.)

in the physician's examination, (c) average BP at the beginning of Baseline Session 1, (d) average BP at the beginning of Baseline Session 2, and (e) average BP at the beginning of Training Session 1. A two-way analysis of variance was carried out for the three treatment groups and five repeated measures of BP in each group. BMD 08V and BMD P2V programs were used in this analysis and in subsequent statistical analyses (University of California, Los Angeles, Health Sciences Computing Facility). Results of the analysis of variance showed that baseline differences between treatment groups were not significant for either systolic or diastolic pressure. The three groups had comparable BP values prior to the beginning of active treatment. However, pressure varied considerably under the different conditions of observation. Pressures were highest for the physician's examination and previous medical history and lowest for the two baseline sessions and the initial training session (Figure 1). A reduction of 5 mm of Hg in systolic pressure and a slight decrease (1 mm of Hg) in diastolic pressure were observed from Baseline Session 1 to Training Session 1. Differences among the five baseline measurements were significant for both systolic and diastolic values, $F(4, 84) = 36.79$, $p < .01$; $F(4, 84) = 30.35$, $p < .01$. Systolic blood pressure

averaged over all 24 patients differed by 17 mm of Hg between medical history value (156 mm of Hg) and Training Session 1 (139 mm of Hg); diastolic blood pressure was lower by 11 mm of Hg (94 mm of Hg and 83 mm of Hg, respectively). Reductions of still larger magnitudes (26/15 mm of Hg) were found when the project physician's recordings were compared to the first training session pressures. These reductions were much larger than any observed during the course of the actual treatment sessions. These data indicate the potency of environmental influences on BP. They also point out the issue of proper baseline determinations and habituation as factors to be accounted for in evaluating the effects of treatment programs of this kind.

Treatment Data

Average systolic pressures for each training session are shown in Figure 2. Also shown are the average systolic pressures for the baseline days and Follow-up Day 1. The graph suggests that the relax group decreased in pressure and the other two groups increased in pressure, comparing the baseline days and Training Day 1. Several preliminary analyses of variance were computed to examine this apparent differential trend. First, an analysis of variance

Figure 2. Mean blood pressure (measured in millimeters of mercury; mm Hg) per session in the three treatment groups. (EMG = electromyogram.)

was carried out for the three treatment groups, comparing Baseline Session 2 and Training Session 1. Neither the interaction between treatment and session nor the session difference were significant. Second, the decrease in systolic BP for the relax group by itself was not statistically significant. Third, an analysis of covariance for the values during the 8 training days adjusting for differences in Baseline Day 2 did not yield a significant treatment effect or a significant Treatment \times Session interaction. Therefore, the treatment data were analyzed without adjusting for baseline values, which were not significantly different between treatment conditions.

The primary treatment data consisted of the systolic pressures obtained during eight sessions of training, 20 values per session, with each value being the median systolic pressure derived from the constant cuff method for each 60-sec trial period. An analysis of variance was carried out for the three treatment groups with repeated measures for eight sessions and 20 trials within each session. A significant main effect was obtained for trials, $F(19, 399) = 15.72$, $p < .01$. On the average, pooling sessions and groups, the initial value in a session was 140.2 mm of Hg, and the 20th value was 136.8 mm of Hg. No other main effects or interactions were statistically significant.

Although the overall analysis of variance for training data indicated no significant effects between groups, inspection of the curves suggested that each treatment group showed a somewhat different pattern of apparent change or habituation over training sessions. For purposes of description only, an analysis of variance for trends was used to examine change over the course of treatment in each group separately. Only linear and quadratic trends were considered. Of the three treatment conditions only BP showed a significant main effect for sessions, $F(7, 49) = 2.52$, $p < .03$. The quadratic effect for sessions was also significant in this group, $F(1, 7) = 24.87$, $p < .002$. In accord with results presented earlier, each group showed a highly significant main effect for trials. Significant linear trends for trials occurred in EMG and relax, considering all sessions or the first six sessions only. The linear trial trend was not significant for the BP group; however, the quadratic trend for trials was significant in this group for all sessions.

Table 2 gives the average 1st and 20th pressure value over Baseline, Training, and Follow-up 1 days. As can be seen in the table, reductions in pressure over the 20 trials within a session were larger in baseline sessions than in training sessions. An analysis of variance comparing Baseline Session 2 with Training Session

Table 2
Systolic Blood Pressure: First and Last Trial Values

Session		Treatment group			All subjects
		BP	EMG	Relax	
Baseline	1	141-136	142-134	142-142	142-138
	2	138-134	140-132	145-136	141-134
Training	1	143-142	142-140	137-136	141-139
	2	140-139	141-137	138-134	140-137
	3	138-137	145-140	138-133	140-137
	4	137-137	138-137	140-138	138-137
	5	137-136	141-134	139-134	139-135
	6	134-128	141-140	138-132	138-133
	7	143-142	143-140	139-133	142-138
	8	143-139	146-143	139-133	143-138
Follow-up	1	139-135	136-130	137-134	138-133

Note. BP = blood pressure, measured in millimeters of mercury; EMG = electromyogram. $n = 8$ for each group.

sion 6 (a session showing a good effect) supports this conclusion ($p < .01$). In Baseline 2, systolic pressure started at 141 mm of Hg in Trial 1 and ended at 134 mm of Hg in Trial 20. Comparable values for Session 6 were 138 mm of Hg and 133 mm of Hg.

Table 2 also reveals the other patterns discussed above. The relax data appeared remarkably uniform from session to session, with Trial 1 values varying from 137 mm of Hg to 140 mm of Hg to 139 mm of Hg over sessions and with reductions in pressure over trials varying from 1 mm of Hg to 6 mm of Hg. The BP group showed little decrease over trials, with the exception of Session 6, and the previously noted trend toward reduction over Sessions 1-6, from 143 mm of Hg to 134 mm of Hg for Trial 1 and from 142 mm of Hg to 128 mm of Hg for Trial 20. Findings in the EMG group were less consistent. In this group, Trial 1 values varied up and down, and reductions during sessions varied from 1 mm of Hg to 7 mm of Hg.

Finally, the treatment session data were re-analyzed for the effects of individual differences in lability and medication. Two separate analyses of variance were carried out, dividing each treatment group into two equal subgroups on the basis of lability and medication (Table 1).

In the lability analysis of variance, a significant three-way interaction occurred for Session \times Trials \times Lability, $F(133, 2394) = 1.27$, $p < .02$. Although this interaction is difficult to interpret, it appears from the data

that labile patients showed more variable, including occasional larger, reductions in pressure over trials and over sessions than did nonlabile patients. These differences were not related to treatment condition. As for medication, three significant interactions were obtained: (a) Trials \times Medication, $F(19, 342) = 1.83$, $p < .02$. On the average, for all treatments, medicated patients showed a slightly greater reduction (about 2 mm of Hg) in systolic pressure from Trial 1 to Trial 20 than did nonmedicated patients. (b) Session \times Treatment \times Medication, $F(14, 126) = 1.92$, $p < .03$. Patterns of change over sessions differed for the three groups according to medication, but no clear interpretation can be arrived at. (c) Session \times Trials \times Treatment \times Medication, $F(266, 2394) = 1.38$, $p < .01$. A four-way interaction such as this can only be speculated about. Examining the first and last trials for each treatment group broken down according to medication, we find that in general non-medicated patients in the BP group showed greater within-session reductions in pressure and increases in these reductions over sessions than medicated patients. In EMG, medicated patients seemed to do consistently better over sessions in terms of pressure reduction. In relax, the trends were about the same in both medicated and nonmedicated patients.

Associated Changes During Treatment

Data on HR in beats per minute were available on each trial during the training sessions.

Table 3
Physiological Changes on Training Day 6

Measure	Treatment group		
	BP	EMG	Relax
BP	-6.0	-1.0	-6.0
Forearm EMG (μ v)	-4.4	-4.4	-10.6
Frontalis EMG (μ v)	+4.4	-12.2	-23.1

Note. BP = blood pressure, measured in millimeters of mercury; EMG = electromyogram.

An analysis of variance comparable to the one carried out on systolic pressure was done. No significant effects related to treatment group were found. As in the case of systolic blood pressure, a significant main effect for trials was observed, $F(19, 399) = 115.33$, $p < .001$. On the average, there was a 3-bpm decrease in HR during sessions from Trial 1 to Trial 20. Separate analyses of each group did not reveal any significant trends over sessions for any group.

Integrated EMG was recorded from both frontalis and right forearm muscles during all baseline and training sessions. An analysis of the change in EMG from Trial 1 to Trial 20 was carried out on Training Session 6 data. Although mean systolic BP of the three groups varied on that day (Figure 2), the change in systolic BP from Trial 1 to Trial 20 was not significant.

Table 3 gives the average systolic BP change, average forearm extensor EMG change, and average frontalis EMG change from Trials 1 to 20 on Day 6. No significant differences between the groups were found in forearm EMG activity. A Link-Wallace shortcut analysis of variance (Mosteller & Bush, 1954) revealed a significant difference for frontalis EMG activity between the BP and relax groups ($p < .05$). Differences in frontalis EMG activity between BP and EMG and EMG and relax were not significant. These data suggest that comparable reductions in BP can be achieved with differing skeletal muscular responses.

Follow-up Data

Turning to the 6-week follow-up data, no significant differences were obtained between groups. Average systolic and diastolic values were quite comparable (Figure 2), and the first and last trial values were also very similar

(Table 2) from group to group. Comparing these values to the medical history or to initial value obtained by the physician, the reductions in pressure for all subjects were 18/8 mm of Hg and 27/17 mm of Hg, respectively. However, comparing these same follow-up values to the initial values obtained at the beginning of the first training session (actual third pretraining visit of patients to the laboratory), the reductions were quite small—6 mm of Hg systolic and 3 mm of Hg diastolic. Whatever benefit there may have been during the training itself, it appears to be of a small magnitude. It is clear that significant reductions in pressure had already occurred prior to the actual inception of treatment, probably as a result of habituation to the laboratory situation (see Figure 1). The apparent reduction in pressure for the relax group at the time of the 6-week follow-up as compared with the baseline days (see Figure 2) was not statistically significant.

In the 1-year follow-up, only about half of the total sample of patients returned for evaluation: 7 BP, 3 EMG, and 3 relax. At this time, the initial in-laboratory average pressures for the three groups were, respectively, 138/88 mm of Hg, 148/92 mm of Hg, and 138/91 mm of Hg. Given the small samples, it is not possible to determine whether the groups differed significantly at this time. The average pressure for the 13 patients was 141/90 mm of Hg, about 3/3 mm of Hg higher than the level obtained at the 6-week follow-up and at the beginning of Training Session 1 (Figure 1).

Discussion

The purpose of this study was to compare the effectiveness of three different, purely behavioral, means of lowering blood pressure in patients with essential hypertension. It was expected on the basis of previous studies that the procedures would be effective to some degree. This was not the case. There was little evidence, either during the course of the treatment sessions or in the follow-up evaluations, of significant reductions in pressure. Considering the initial pressure values obtained immediately prior to the beginning of training as a baseline, the average reduction for all 24 patients at the time of the 6-week follow-up was 1 mm of Hg systolic and 2 mm of Hg diastolic. On the basis

of data available from about half the sample at the time of the 1-year follow-up, pressures were back to pretreatment levels. No one treatment procedure was obviously better than any other. Within sessions, they all resulted in significant reduction of pressure of about 4 mm of Hg systolic on the average.

For each of the methods used in this study, several earlier studies have been cited that reported average reductions in pressure ranging from 5% to 15% of pretraining baseline values. The failure to obtain even small reductions in the present study is therefore quite puzzling. Some speculations can be offered as the reasons for this failure and the apparent inconsistency between previous and present findings. Consider the BP group findings. In this group, there was only a small reduction in systolic pressure over the 20 trials within any one session, typically 1 mm of Hg. Benson et al. (1971) reported average within-session reductions of 4.8 mm of Hg in seven patients, and this value is in accord with the change observed in normotensive subjects (Shapiro et al., 1969). Both of the latter studies contained simple systolic pressure feedback. Since we know that patients can respond positively to systolic feedback by itself, it may be that the additional task of training to reduce HR at the same time made it more difficult for these patients to reduce BP. The average HR in these BP patients was not elevated, possibly further adding to the difficulty. Previous studies involving behavioral treatment of hypertension through direct BP biofeedback used patients with sustained hypertension whose pressures were usually higher than subjects studied here. Subjects in the Benson et al. (1971) study showed average pretraining systolic pressures of 165 mm of Hg, and Goldman et al. (1975) reported a sample average of 167 mm of Hg, whereas our subjects showed average pretraining pressures of 141 mm of Hg during the first three laboratory exposures prior to training. It is possible that the effectiveness of behavioral treatment follows the law of initial values (Wilder, 1957), and that only patients with relatively elevated pressures will show substantial benefit from such treatment. Furthermore, although the average pressures for our sample of patients were relatively high as recorded in various medical examinations prior to treatment, the values were

considerably reduced in the quiet, relatively nondemanding laboratory conditions. The usefulness of biofeedback training or of other methods of behavioral control under conditions in which the symptom is not shown in full force may be questionable.

Another difference between this study and previous reports is that the present investigation gave all subjects a rather limited amount of training and attention. Only 8 training sessions were used in the present study as compared to up to 34 sessions in the Benson et al. (1971) study or 42 sessions in the Kristt and Engel (1975) study. It is of interest, however, that the one subject studied by Benson et al. (1971) who had both similar baseline pressures and number of training sessions showed a reduction in pressure similar to that of subjects in our study. Also, in the Goldman et al. (1975) study in which only nine treatment sessions were used, systolic reductions of only 4% were observed although diastolic changes were much larger.

As for the EMG group, we asked these patients to lower muscle activity in two sites, forearm and forehead. This double requirement may have contributed to the apparent difficulty in achieving total muscular relaxation. In any case, the EMG group data are quite variable and inconsistent with earlier reports of success. We could speculate that some other more potent ingredient such as the suggestion to relax in the treatment process or an expectancy of success was present in the other studies and missing in ours.

In the relax group, the pressure data were remarkably consistent from day-to-day treatment and relatively consistent within sessions. It seems that the relax group involves the least task or problem-solving orientation of the three procedures. This is reflected in the apparent immediate reduction in pressure at the very beginning of Training Session 1 and the consistent 4-5 mm of Hg reduction in pressure from beginning to end of each session. The lack of pressure reactivity reflects the passive, relaxed stance involved in the procedure, and the data attest to the ability of patients to comply with the instructions that seem to enhance their ability to relax and to show rapid habituation to the treatment situation. If there is any lasting therapeutic benefit to such a pro-

cess, it was not revealed in any session-by-session trend or in the follow-up data. Because of its inherent simplicity, however, the meditation relaxation procedure could be seen to have an advantage over other methods.

These results, in light of the interpretations and possible explanations offered here, suggest possible refinements in future research. First, we need more systematically to segregate labile from fixed patients, to account more thoroughly for the effects of medication, and to make a more thorough assessment of cardiovascular status to determine the suitability of feedback of different pressure (diastolic, systolic) or cardiac (heart rate, cardiac output) indices, whether singly or in patterns. Second, the arbitrary use of a fixed number of training sessions may not be adequate, and more than eight sessions may be required. Third, the design of treatment procedures must carefully consider the degree to which task involvement should play a part in the process. For some patients, simple passive, nontask conditions, such as mediation relaxation, may be appropriate. In others for whom abnormal reactivity to stressful situations or other eliciting events is a factor, the learning process could well incorporate a task, such as in biofeedback for pressure reductions, or a task involving alterations of physiological response in coping with stressful stimuli (Sirota, Schwartz, & Shapiro, 1974).

Finally, rather large differences were observed between pressure levels obtained in the medical history and in our physician's examination as compared with the levels obtained in quiet laboratory conditions, particularly after a few baseline nontask recording sessions. These differences range up to 20 mm of Hg systolic and 15 mm of Hg diastolic. They attest to the potency of real-life variables (e.g., doctor's examination) versus the lack of potency of nonstimulating laboratory conditions. Such variability has been noted repeatedly in the literature (Julius & Schork, 1971). Engel (Note 1) has suggested that the physician effect or habituation to the physician and medical situation may account in part for the placebo effect noted in hypertensive research (Miller, 1974). The commonly reported reductions in pressure in many behavioral treatment studies may also reflect this process of habituation. It is obvious that we need to pay more attention to the

sources of variability in blood pressure, particularly in patients with essential hypertension, as these sources may tell us about the nature of the disorder and give us clues about the design of relevant behavioral treatment procedures and appropriate methods of evaluating treatment effects.

Effects of Transcendental Meditation and Muscle Relaxation on Trait Anxiety, Maladjustment, Locus of Control, and Drug Use

David C. Zuroff and J. Conrad Schwarz
University of Connecticut

Sixty undergraduate volunteers were randomly assigned to receive training in transcendental meditation (TM), training in a muscle relaxation technique, or no treatment. The training in muscle relaxation was designed to be maximally similar in structure and atmosphere to training in TM. Measures of trait anxiety, locus of control, maladjustment, and drug use were collected before and after the 9-week treatment period. On a behavioral measure of trait anxiety, the scores of all three groups decreased equally, but on a self-report measure the TM subjects reported steady decreases in anxiety, whereas the scores of the other two groups remained unchanged. There were no differences in maladjustment, locus of control, or drug use as a function of treatment. Although TM subjects held higher expectancies for benefits, and were slightly more regular in practicing their technique, individual differences in expectancy and frequency of practice were not correlated with degree of reported anxiety reduction. It is concluded that TM may reduce trait anxiety, but it has not been shown to be of value in inducing general personality change.

Studies of the effectiveness of transcendental meditation (TM) have generally lacked the methodological rigor and sophistication that is now expected in studies of psychotherapy outcome (Smith, 1975). Three particularly pervasive flaws have been the following: the failure to obtain initially equivalent treatment and control groups by random assignment of subjects, the tendency to rely exclusively on self-report measures, and the failure to use "placebo" treatments to control for nonspecific treatment effects. It is interesting to note that with the exception of Smith's (1976) methodologically sound study, previously published research has been uniformly favorable to TM.

This article is based on portions of a thesis submitted by the first author in partial fulfillment of the requirements for the MA degree at the University of Connecticut, 1975. This investigation was supported by grants from the University of Connecticut Research Foundation, the University Computer Center, and Research Grant GS-31020X from the National Science Foundation.

In particular, changes in the "healthier" direction have been reported for each of the variables of interest in the present study: anxiety (Ballou, 1973; Ferguson & Gowan, 1973; Hjelle, 1974; Orme-Johnson, Arthur, Franklin, O'Connell, & Zold, 1973); maladjustment (Ferguson & Gowan, 1973; Hjelle, 1974; Seeman, Nidich, & Banta, 1972); locus of control (Hjelle, 1974); and marijuana use (Shafii, Lavelly, & Jaffee, 1974).

These results must be interpreted in light of the design flaws mentioned above; none of these studies used a placebo control group, and only Ballou (1973) achieved a true experimental design. Based on his review of these and other studies, Smith (1975) rightly concluded that methodological flaws in the studies reviewed were such that there "is not clear evidence that meditation is in and of itself therapeutic" (p. 562).

Smith (1976) attempted to overcome the limitations of these studies by randomly assigning students who had volunteered to obtain free treatment for reducing anxiety to receive either TM, no treatment, or a treatment designed to be equivalent to TM in

terms of both expectations for benefits and the repeated quiet sitting involved in meditation. Using the Spielberger State-Trait Anxiety Inventory (Spielberger, 1972), the Tennessee Self-Concept Scale, and the Sixteen Personality Factor Questionnaire, Smith found that on virtually every measure of psychopathology, the two treatment groups improved significantly more than the untreated controls. However, the TM subjects showed no more improvement than subjects exposed to the placebo treatment. This finding was replicated in a second experiment comparing a TM-like meditation technique with an "antimeditation" technique involving the active generation of positive thoughts. Smith (1976) concluded that the crucial therapeutic agent in meditation is not the focusing of attention on the mantra (a Sanskrit word personally prescribed for each meditator) but rather some combination of just sitting and the expectation that the technique one is practicing is therapeutic.

Although Smith's study is weakened by the high dropout rate—59% for TM and 53% for the control treatment in the first study—and the reliance on self-report measures, it certainly casts considerable doubt on earlier claims that TM has specific treatment effects on anxiety and, more globally, on psychological adjustment.

The present study, like Smith's, provided for random assignment of subjects to the three experimental groups and for a nonspecific effects control group. However, the muscle relaxation technique was designed to control not only for the nonspecific effects of TM, including placebo effects and the effects of simply sitting regularly, but also for its demonstrated properties of autonomic arousal reduction (Wallace, 1970).

Method

Subjects

Subjects were recruited from the introductory psychology course at the University of Connecticut for "an experiment concerning transcendental meditation and a muscle relaxation technique." Students who had prior training in any kind of meditation were not eligible, so our sample may not be fully representative of those who independently seek instruction in TM. However, our subjects were interested in meditation, and in fact almost all subjects in the final sample stated that they had volunteered hoping to be assigned to the TM group.

One hundred fifty students volunteered, and from these we randomly selected 30 males and 31 females who were not receiving therapy or counseling: 1 female dropped out of the TM group shortly before training. All subjects were required to post a \$10 deposit, forfeitable to the scholarship fund if he/she failed to complete all the testing. Sixty-seven percent of the subjects were 18 years old; 75% were in their first or second semester; 66% were firstborn or only children; and 52% were Catholic by birth.

General Experimental Design

Subjects were randomly assigned to receive either training in TM, training in muscle relaxation, or no treatment. Measurements were made before and immediately after the training, at the midpoint of the treatment period, and again at the end of the 9-week treatment period.

Transcendental Meditation

Instruction in TM, which consists of two group lectures of about 1 hour each, 1 hour of individual instruction in the technique itself, and three additional 1-hour group meetings, was provided by experienced initiators from the Storrs branch of the Student International Meditation Society. Throughout the training period it is repeatedly stressed that TM is easy, natural, and spontaneous, and that regular practice will inevitably bring a wide range of benefits. The only departure from the standardized procedure introduced by the experiment was the use of grant funds to pay subjects' \$45 initiation fees.

Muscle Relaxation

The training procedure in muscle relaxation was designed to duplicate as nearly as possible the structure and atmosphere of TM instruction. Considerable attention was devoted to making the treatment equivalent to TM in credibility and attractiveness and to heightening subjects' expectations for benefits. The training in muscle relaxation followed the same sequence and provided the same amount of contact with instructors as the training in TM.

At the two initial lectures, the first author presented a rationale for the technique, which suggested that "tension" was the root cause of human unhappiness and that muscle relaxation would reduce both mental tension and, in the long run, chronic physical tension or "body armor." The experience of muscle relaxation was described as one of pleasant relaxation in which the mind floats off gently, returning refreshed and renewed.

Subjects were taught muscle relaxation by three advanced doctoral students in clinical psychology (two males, one female) and a female doctoral student in Family Life Education who held a master's degree in clinical psychology.¹ They were all experienced in teach-

¹ We would like to thank John Dufresne, Ron Lajoy, Margaret Nichols, and Ruta Teisman for their work in teaching the muscle relaxation subjects.

ing the technique and were supervised by a licensed clinical psychologist. They followed Paul's (1966) instructions for inducing muscle relaxation, spending between 20 and 40 minutes with each subject. Paul's (1966) procedure is an accelerated form of Jacobson's (1938) technique that involves alternately tensing and releasing muscle groups until a state of deep muscle relaxation is achieved. Subjects were instructed to practice at home for approximately 20 minutes twice per day.

The group meetings, which were held during the 3 evenings following the individual instruction, included discussion of problems encountered by the subjects, additional lecture material, and group practice of muscle relaxation. The lecture material consisted of scientific-sounding explanations of how muscle relaxation reduces muscle tension and promotes personality growth and stressed the simplicity, ease, and inevitable efficacy of the technique.

No Treatment Control

Subjects in the no-treatment control group were not given any training nor were they asked to alter their lives in any special way. They were exposed to virtually the same questionnaires and measurement procedures as subjects in the other groups.

Measures

Assessments were made in five areas: background and personality variables; expectancies; extent of arousal reduction; psychological maladjustment; and trait anxiety. Both behavioral and self-report measures of trait anxiety were used.

Background and personality variables. All subjects were administered Rotter's (1966) Locus of Control scale; the Social Desirability Scale (Crowne & Marlowe, 1960); and questionnaires concerned with demographic characteristics, previous and current drug and alcohol use, and experiences with TM and muscle relaxation.

Expectancies. The expectancy questionnaire included 25 possible benefits that muscle relaxation and TM subjects rated on an 11-point scale (0%-100%, in 10% intervals) for likelihood that regular practice would lead to that benefit. The ratings were summed to yield a total expectancy score. The items were drawn from the four general areas of improvements in subjects' emotional lives, achievements, interpersonal relations, and health. Some sample items are "lessened feelings of anxiety"; "deeper understanding of material in academic courses"; "more satisfying relationships with those close to you"; and "improved body posture."

Arousal reduction. Autonomic arousal was conceptualized as an abstract dimension, or factor, that reflects the common variance of many physiological response systems (Berlyne, 1967). Ideally, such a factor would be assessed by measuring a variety of different physiological indices, since any one index will share only some of its variance with the hypothetical construct of arousal. However, since we were not equipped to monitor several physiological channels, pulse rate alone was used as an approximate index of arousal. This particular variable

was selected because it has been shown to be affected by both muscle relaxation (Paul, 1969) and TM (Wallace, 1970), and it is generally considered to be one of the indices related to arousal level (Berlyne, 1967).

The extent of pulse rate reduction achieved by subjects while meditating, practicing muscle relaxation, or for the control subjects, simply resting with eyes closed, was monitored during an 18-min testing period. Subjects' pulses were measured by a light-sensitive plethysmograph (Grass Model 76604) attached to the index finger of the nondominant hand. The transduced signal was recorded by a Grass Model 76101 polygraph. The pulses were recorded for 20 sec immediately before the beginning of the testing period and for another 20 sec between 17 min 25 sec and 17 min 45 sec of the period.

Psychological maladjustment. Rotter's Incomplete Sentences Test, the measure of overall psychological maladjustment, was scored by the first author using Rotter and Rafferty's (1950) scoring manual; he was blind to both group and time of administration.

Trait anxiety (self-report). Each week of the experiment, subjects completed Zuckerman's (1960) Adjective Check List (ACL) scale of anxiety with instructions to check the adjectives that described how they felt "this week." In addition, the S-R Inventory of Anxiousness (Endler, Hunt, & Rosenstein, 1962) was administered on four occasions. This instrument requires the subject to indicate on a 5-point scale how strongly he or she would react with each of 14 common "anxiety" responses (sweaty palms, nausea, etc.) in each of 11 different situations. The ratings were summed to yield an overall index of trait anxiety.

Trait anxiety (behavioral). In response to the need for a behavioral measure to supplement the self-report measures of trait anxiety, the Behavioral Anxiety Measure (BAM) was developed by modifying a procedure used by Rehm and Marston (1968). The BAM consists of 10 tape-recorded situations, each of which contains a short description of a social situation followed by a line of dialogue spoken by someone in the situation. The subject's task is to respond to the line of dialogue. Thirty seconds were allowed for each situation and response unit. Subjects' performances were videotaped through a one-way mirror and rated using a checklist of anxiety indicators derived from that of Paul (1966).

The details of the procedure were as follows: The experimenter first presented written instructions, which emphasized that the subject was to respond "just as you would if the situation were actually happening" and that his or her performance would be rated for "overall psychological adjustment." The experimenter, who remained in the room with the subject throughout the testing, then played a demonstration tape of three situations and gave a prearranged sample reply for each.

Two sets of situations, each with a male and a female form, were prepared from an initial pool of 48 situations representing the four general areas of professor-student, parent-student, heterosexual, and same-sex peer relationships. This pool was submitted to 46 male and 42 female introductory psychology students, who rated each situation for how uncomfortable it would make them. The final sets of situations were selected so that the four forms (A-male, A-female, B-male, B-female) would be nearly equal in mean discomfort rating. A

sample situation (professor-student) is: "You have a large, 9:00 lecture class that you tend to be late for. Usually the professor just gives you a dirty look, but this morning as you enter the lecture hall she says, 'alright, how come you're late *again* today?'"

Nine relatively specific behaviors were chosen as anxiety indicators: head held downcast, abrupt head movements, swaying, extraneous arm and hand movements, arms held rigidly, hands restrained, failure to reply, blocking of speech, and extraneous comments. The raters practiced scoring videotapes of volunteer undergraduates until interrater reliability exceeding 70% was established for each of the nine items.

Three or four raters, blind to the subjects' group memberships, viewed each videotape and made two ratings for each of the 10 situation-response units. The first rating was based on the subject's behavior during the first 15 sec of the interval, and the second was based on the behavior of the final 15 sec. The score for the test was simply the sum of the number of 15-sec blocks in which each behavior was observed.

Procedure

Subjects received groups of measurements at six testing sessions: pretreatment, pretraining, posttraining, midtreatment, Posttreatment 1 and Posttreatment 2. (Posttreatment 1 and Posttreatment 2 were separated by approximately 1 week.) There was a delay of approximately 2 weeks between the pretreatment measures and the measures administered immediately before training (pretraining). The Locus of Control scale, the Social Desirability Scale, the first questionnaire, and the Incomplete Sentences Test were group administered at the pretreatment session; the Locus of Control scale and the Incomplete Sentences Test were readministered at Posttreatment 2, along with the second questionnaire. The S-R Inventory of Anxiousness was administered at pretraining, posttraining, midtreatment, and Posttreatment 1. The BAM was administered at pretraining and Posttreatment 1, and at Posttreatment 1 it was followed by the arousal-reduction measurement. All subjects completed a weekly ACL anxiety scale. In addition, subjects in the two treatment groups completed the expectancy questionnaire four times during their training and again at Posttreatment 2, and they provided a weekly report of the number of times they had meditated or relaxed.

The experimenters for the BAM were three male and three female undergraduates. A randomly selected half of the males and females within each group received BAM Set A at pretraining and Set B at Posttreatment 1 and the remaining subjects received the sets in the opposite order.

In accordance with the Student International Meditation Society's requirement of 15 days of abstinence from drugs prior to initiation, all subjects were asked to refrain from using drugs for the 2 weeks separating the pretreatment testing and the first day of training.

Results

The results of the study are presented in the following order: behavioral anxiety measure,

self-report anxiety measures, other outcome variables, and possible origins of differential treatment effects.

Behavioral Anxiety Measure

Interrater reliabilities for the scores on the BAM were computed using Pearson product-moment correlations. The mean reliabilities at pretraining and Posttreatment 1 were, respectively, .80 and .92. Using the Spearman-Brown formula for three independent raters, the reliabilities of the averaged scores were estimated to be .92 at pretraining and .97 at Posttreatment 1.

Test-retest reliabilities were computed using the control subjects' scores, and the reliability of the BAM scores was found to be satisfactory ($r = .58, p < .05$).

The BAM scores were analyzed in a repeated measurements analysis of variance design with one between (groups) and one within (time) factor.³ The time effect alone was significant, $F(1, 57) = 29.08, p < .001$. Inspection of the means revealed that there was an overall tendency to exhibit less anxiety at the second BAM testing but that there were no between-group differences in this regard. Thus, the behavioral anxiety measure provided no evidence of treatment effects of either muscle relaxation or TM on subjects' trait anxiety.

Self-report Anxiety Measures

The weekly ACLs were averaged over intervals of 2 weeks to obtain six biweekly average ACL scores for each subject; the first 2-week interval extended through the first day after the personal instruction of treated subjects and essentially constitutes a pretraining baseline.

A repeated measures analysis of variance disclosed a main effect for time, $F(5, 284) = 5.33, p < .001$, and a trend toward a groups effect that nearly reached the conventional significance level, $F(2, 57) = 3.06, p = .055$. Although the control group consistently reported greater anxiety than the other two groups,

³ All analyses were carried out using an unweighted means solution for unequal *N*s. Missing data were estimated by the Data-Text program, and error degrees of freedom were adjusted accordingly.

Table 1

Means of Total Scores on the S-R Inventory of Anxiousness by Group and Sex

Group	n	Administration			
		Pretraining	Posttraining	Midtreatment	Posttreatment 1
Muscle relaxation					
Males	10	336.0	331.0	325.7	332.4
Females	10	371.0	374.5	355.6	351.9
Transcendental meditation					
Males	10	353.6	328.3	304.6	294.2
Females	9	384.2	369.3	346.1	344.3
Control					
Males	10	362.4	348.9	334.8	337.1
Females	11	434.4	435.9	438.4	436.6

there was a downward trend in anxiety across the groups. A trend analysis (Meyers, 1972) indicated that there was a significant linear component to this trend, $F(1, 57) = 10.41$, $p < .001$.

The total scores for the S-R Inventory of Anxiousness were analyzed in a repeated measures analysis of variance design with groups and sex as between-subjects factors. Significant effects were found for sex, $F(1, 54) = 12.20$, $p < .001$; groups, $F(2, 54) = 4.13$, $p < .05$; time, $F(3, 161) = 14.56$, $p < .001$; and the Groups \times Time interaction, $F(6, 161) = 3.53$, $p < .01$. It can be seen from the means (Table 1) that females consistently reported greater anxiety than males and that the control group consistently scored higher than the two treatment groups. The most interesting finding was that although the muscle relaxation and control groups' scores remained essentially unchanged over time, the TM group reported substantial decreases in anxiety. The absence of a triple interaction involving sex indicates that the differential treatment effect found in these data was present equally for males and females. Therefore, the sex factor was dropped from a trend analysis performed to investigate the nature of the significant Groups \times Time effect. The S-R inventory was assumed to have been administered to all subjects on the 1st, 11th, 37th, and 71st days of the experiment, and orthogonal linear ($-29, -19, 7, 41$) and quadratic ($3.85, -1.00, -6.16, 3.31$) coefficients were derived (Meyers, 1972). The linear component of the interaction was found to be significant, $F(2, 57) = 4.72$, $p < .02$, but the quadratic component was not, which indicates

that the decreases in the TM group's reported anxiety occurred steadily over the 9-week treatment period.

Thus, of the two self-report measures of trait anxiety, the S-R inventory provided evidence of a treatment effect of TM, but the ACL did not.

Other Outcome Variables

Maladjustment scores from the Incomplete Sentences Test administered at pretreatment and Posttreatment 2 were analyzed in a repeated measures analysis of variance with groups as a between-subjects factor. The only significant effect was time, $F(1, 56) = 8.18$, $p = .006$, which was associated with an overall decrease in maladjustment scores.

Analysis of subjects' locus of control scores disclosed no significant effects, indicating that the groups neither differed initially nor changed significantly over the course of the experiment.

Subjects' stated frequencies of drunkenness and marijuana use "in the recent past" were collected at pretreatment and Posttreatment 2 and were subjected to another repeated measures analysis of variance. No significant effects were found for either frequency of drunkenness or frequency of marijuana use.

At Posttreatment 2, subjects in the two treatment groups were asked to rate on a 5-point scale how much benefit they felt they had gained in each of eight areas: academic performance, interpersonal relations, health, condition of body and nervous system, decreased drug use, increased energy and vitality, overall happiness, decreased anxiety, and self-

esteem. The first, third, and fifth points on the scale were labeled, respectively, *not at all*, *a moderate amount*, and *a great deal*. The mean ratings of the muscle relaxation and TM groups were compared by *t* tests, and it was found that the only significant difference was for academic performance, with TM subjects reporting greater benefits, $t(18) = 2.51$, $p < .05$. It is noteworthy that the TM group tended to report only "moderate" benefits, with mean ratings ranging from 2.20 (decreased drug use) to 3.32 (increased energy and vitality).

Possible Origins of Differential Treatment Effects

Additional analyses were performed to determine if there were unintended differences between the treatment groups that might have been responsible for the observed differential treatment effect.

Unfortunately, the posttraining arousal reduction data had to be discarded because of equipment problems that remained undetected for numerous subjects. The analysis of variance of the Posttreatment 1 data revealed an overall decrease in pulse rate (M change = 2.8 beats per minute) from the beginning to the end of the 18-minute testing period, $F(1, 57) = 13.78$, $p < .001$, but there was no evidence that meditation produced greater reduction in arousal than muscle relaxation or simply sitting with eyes closed.

The treated subjects' weekly frequencies of practice were averaged over 2-week intervals and analyzed in a repeated measures analysis of variance. Main effects for groups, $F(1, 37) = 6.70$, $p < .05$, and time $F(4, 147)$, $p < .001$ were found, but their interaction was not significant. Both groups decreased in frequency after the first 2 weeks, and although the TM group maintained a consistently higher frequency, the magnitude of the average difference was not great (for TM, $M = 11.5$; for muscle relaxation, $M = 10.2$).

Subjects' total expectancy scores after their training (posttraining) and at the end of the experiment (Posttreatment 2) were used as an index of the nonspecific effects of treatments. Repeated measures analysis of variance disclosed a significant effect for time, $F(1, 37) = 13.52$, $p < .001$, and a trend toward a groups effect, $F(1, 37) = 2.89$, $p = .10$. Both

groups' expectancies decreased over the treatment period. The trend in the groups factor reflected the TM group's higher expectancies and suggests that the treatments may not have been equal in their nonspecific effects.

To determine if the variables on which differences were found between the treatment groups were actually associated with the observed treatment effect of TM, correlations were computed between these variables and residual change scores on the S-R inventory. The change scores were computed from the TM subjects' pretraining and Posttreatment 1 S-R inventory scores, using the linear regression coefficient derived from the entire sample. The correlations between the treatment effect, as measured by the residual change scores, and variables we thought might be related to treatment effect were average frequency of practice, $-.23$; total expectancy, $-.26$; social desirability, $-.20$; psychological adjustment, $.06$; and locus of control, $.53$ ($ps < .05$). It is apparent that the two variables on which the treatments differed, frequency of practice and expectancy, were not significantly related to TM subjects' decreases in trait anxiety.

Discussion

Interpretation of these findings is made difficult by the inconsistency of the results obtained with the three measures of trait anxiety. In particular, it is unclear whether the S-R inventory measured some change in TM subjects to which the other instruments were insensitive or whether that apparent change was an artifact of measurement.

One possibility is that the TM treatment effect was a result of subjects' perceptions that this was "an experiment on TM" and their responses to the implicit demands (Orne, 1969) to report decreases in anxiety. On the other hand, the fact that Social Desirability scores did not predict residual gain scores within the TM groups argues against this hypothesis, since it would be expected that subjects more highly motivated to win the experimenter's approval would report larger decrements. A second possibility is that the decline in anxiety scores indicated changes in subjects' self-images rather than actual changes in trait anxiety. It is difficult to reconcile the self-image interpre-

tation of the S-R inventory results with the failure to find a treatment effect on the anxiety ACL, however, since the ACL is a classic format for eliciting self-images and should have been sensitive to beliefs such as "I don't get so tense anymore." Furthermore, there is some evidence (Otis, 1974) that TM does not affect subjects' self-images.

Thus, although not conclusive, the available evidence favors the view that the S-R inventory measured a real decrease in meditators' trait anxiety. How, then, can we reconcile the positive results obtained from this instrument with the negative results obtained with the ACL and the BAM? A cue is provided by the fact that analyses performed using the response factor scores (Endler et al., 1962) in place of the overall score on the S-R inventory found TM to be more effective than the other conditions in reducing scores on the "distress" factor but not on the "autonomic" factor. Recalling Lang's (1969) distinction among the self-report, behavioral, and autonomic dimensions of anxiety, it seems reasonable to suppose that the distress factor corresponds to the self-report component of anxiety and that our S-R inventory results primarily reflect changes in subjective distress. This implies that although TM may have had no effect on the behavioral or autonomic components of anxiety, or on global self-images of anxiety proneness, it may have reduced subjectively experienced distress in the specific situations tapped by the S-R inventory. If this interpretation were valid, it would follow that TM first affects subjective distress, and, at least over short treatment periods, does not alter overt behavior.

Even if one accepts the conclusion that TM was effective in reducing some aspect of anxiety, it can still be argued that the greater reduction in anxiety reported by TM subjects was due to the operation of a stronger placebo effect rather than to a *specific* effect on TM, since training in TM produced higher expectancies for benefits. The plausibility of this interpretation of the S-R inventory results is reduced by three findings: First, though a significant relationship between expectancy and outcome measures would be expected if the treatment were functioning primarily as a placebo, TM subjects' expectancies immediately after the training period did not signifi-

cantly predict residual change scores on the S-R inventory. Second, subjects' expectancies decreased over the treatment period in which their reported trait anxiety decreased, and it seems unlikely that a treatment could have a strong placebo effect while subjects' confidence in the treatment was waning. Finally, the decreases in anxiety were not abrupt, as would be expected from a placebo effect, but were gradual and continuous, as would be expected from a true treatment effect.

This moderately supportive evidence for the existence of a specific treatment effect of TM is not consistent with Smith's (1976) study, which found TM to be no more effective than a nonspecific effects control treatment, which consisted of sitting passively in a chair. This inconsistency could reflect differences in the measures of anxiety used in the two studies, differences in responses to treatment as a function of the populations studied, or differences between the nonspecific effects control treatments. Smith's subjects volunteered specifically to receive treatment for anxiety, whereas the majority of subjects in the present study were hoping to receive training in TM. It is possible that the groups who received what they were seeking—Smith's two treatment groups and our TM group—responded with reports of decreased anxiety. Another possibility is that the high dropout rate in Smith's study was not random but instead reflected a Treatment \times Subjects interaction in which different subpopulations responded specifically to each treatment, and the nonresponders in each group tended to drop out. Finally, Smith's control treatment may have incorporated a therapeutic ingredient that was absent in this study's muscle relaxation treatment, for example, the pairing of relaxation with continued cognitive activity, the feeling that the technique was easy and enjoyable to practice, or a placebo effect fully as strong as that of TM.

In contrast to previous studies, the present study found TM to have no effect on subjects' scores for locus of control, psychological maladjustment, or frequencies of drunkenness and marijuana use. However, with the exception of the studies by Smith (1975) and Shafii et al. (1974), the earlier results are compromised by weak designs and measures of questionable validity. The results of the last two studies are

not directly comparable to those reported here, because they were obtained with different populations, different measures, and over longer treatment periods. Until further research clarifies the situation, the most that can be said with assurance is that there is at present as much negative as positive evidence concerning the effects of TM on maladjustment and drug use, and there is no sound evidence that it affects locus of control.

In summary, though the results of this study provide some support for the hypothesis that TM is specifically effective in reducing normal college students' experiences of anxiety, it must be remembered that negative results were obtained with the behavioral measure of trait anxiety and with measures of locus of control, psychological maladjustment, and frequency of drunkenness and marijuana use, and that the technique tended to be rated as only "moderately" helpful with general life problems. It appears, therefore, that TM has been oversold by its proponents, and unless it is shown that long-term practice does lead to great benefits, it should be considered irresponsible to advertise TM as a panacea.

Personality Correlates of Continuation and Outcome in Meditation and Erect Sitting Control Treatments

Jonathan C. Smith
Roosevelt University

In a 6-month double-blind study, 49 anxious college student volunteers were assigned to transcendental meditation (TM) and 51 to a control treatment, periodic somatic inactivity (PSI). The control treatment was carefully designed to match the form, complexity, and expectation-fostering aspects of TM, but it incorporated an exercise that involved sitting erect with eyes closed twice daily rather than sitting and meditating. For each treatment 30 demographic and pretest personality variables were correlated with continuation in treatment and outcome defined in terms of trait anxiety change scores. As predicted, the TM dropout was more disturbed and less self-critical than the person who continued meditating. For TM, outcome correlated significantly with anxiety, Sizothymia (16 Personality Factor Questionnaire, Factor A), and Autia (16 Personality Factor Questionnaire, Factor M). Contrary to what was predicted, there was virtually no overlap between the variables correlated with continuation and outcome for TM and for PSI. It is concluded that differing treatment rationales rendered the treatments appealing, credible, and effective for different types of individuals.

Meditation research seems destined to repeat the sins of a generation of psychotherapy outcome research. In both areas the tendency has been to ask "does it work?" As Bergin (1971) has chronicled, this amorphous question has littered the journals with controversial and ambiguous results. Instead, Paul (1967) suggested:

The question towards which all outcome research should ultimately be directed is the following: *What treatment, by whom, is most effective for this individual with that specific problem, and under which set of circumstances?* (p. 111)

Meditation researchers have tended to ignore such questions of specificity (Smith, Note 1).

A surplus of studies show that individuals generally display reductions in trait anxiety after learning meditation (Smith, 1975b). However, not everyone benefits, and up to half discontinue (Smith, 1976; Otis, Note 2). To date no one has systematically explored

the type of person who gains from meditation, and only one person, Otis (Note 2), has looked at the meditation dropout. On the basis of two questionnaire studies, Otis found that subjects who stop practicing transcendental meditation (TM) compared with those who continue feel "less positive about themselves," have "more serious problems," and are more "withdrawn, irritable, and anxiety ridden." In addition, he suggested that subjects who continue with TM are somewhat less disturbed, although they may admit to more problems; that is, they may be more self-critical.

The present study examined characteristics of subjects who drop out of TM and subjects who continue practicing for up to 6 months and who display significant reductions in trait anxiety. On the basis of Otis's findings, it was predicted that subjects who continue practicing TM, compared with those who discontinue, are at pretest less disturbed, less anxious, and less withdrawn but more self-critical. Also, a previous study based on the same subject sample used in the present study (Smith, 1976) concluded that TM and a yogalike treatment involving sitting erect are equally

psychotherapeutic, and that the therapeutic processes operating in both are the same—some combination of expectation of relief and daily sitting. For this reason it was predicted that the correlates of continuation and outcome are the same for TM and the treatment involving sitting erect.

Method

Procedure

The present study used data collected in a previous study (Smith, 1976) that compared the psychotherapeutic effects of TM and a control treatment, periodic somatic inactivity (PSI). Subjects were 100 (51 male, 49 female) Michigan State University students who were suffering from a high level of trait anxiety. All were carefully screened for motivation, were not involved in psychotherapy, and had at no time practiced meditation or yoga. Mean age was 22.

All subjects were pretested, and 49 were randomly assigned to TM and 51 to PSI. TM was taught by two official TM instructors from the Students' International Meditation Society and was identical to ordinary TM in every respect except that it was offered free. The TM technique involves sitting erect with feet flat on the floor and eyes closed while passively and continuously attending to a special thought called a "mantra." This is done for 15–20 minutes twice daily. Complete TM instruction includes two introductory lectures that outline supporting theory and research, a 15-day drug fast, standardized individual instruction, 3 days of follow-up instruction and discussion, and monthly follow-up checking.

PSI was designed to control for the potentially therapeutic effects of daily sitting and expectation of relief. Specifically, the treatment matched TM in every respect with one exception—instead of sitting and meditating, the instructions were to simply sit. Subjects were told that while in this position they could think about anything (even worry) and the technique would still work. Like TM, PSI instruction began with two introductory lectures that outlined a rationale explaining why sitting twice daily should be an immensely effective cure for most forms of psychopathology. In addition, bogus research was presented to support the claims made. Between lectures, subjects participated in a 15-day fast from illegal drugs. After the fast and lectures, subjects were individually initiated and met for 3 days of follow-up checking. PSI was taught double blind; both the subjects and the instructor were deceived into believing that the treatment was legitimate and widely researched and not a bogus control treatment.

One important feature of PSI was its rationale. Care was taken to construct a rationale that was credible and complex. To enhance credibility, actual psychological concepts and research were woven together in a superficially elegant manner. That not one component of PSI theory was false or deceptive (although supporting "process" and "outcome" research was faked) makes

it unique among bogus treatment rationales. A summary of the rationale given to subjects is presented below (Smith, 1975a):

Built into life are factors that disrupt inner calm and generate and maintain anxiety. Research has shown that one of these factors is the desynchronization of circadian rhythms, daily rhythmic changes in physiological functioning. PSI works to bring circadian rhythms into synchrony.

The way PSI works is complex. All physical activity, no matter how small, generates a fatiguelike and stresslike nonspecific physiological by-product called *reactive inhibition*. Simple physical inactivity tends to trigger the automatic dissipation of reactive inhibition. Such dissipation appears physiologically as a decrease in physiological activity and as a small dip or signature in the constellation of circadian rhythms. PSI involves remaining physically inactive for 15 to 20 minutes at the same time each day. The result is that regular inactivity-induced signatures appear at and become classically conditioned to the same point in one's circadian rhythms each day. As one continues practicing PSI, conditioning continues, overlearning occurs, "dips become conditioned onto dips," and gradually, and automatically, the associated physiological changes become deeper and deeper.

The regular appearance of inactivity-induced signatures in circadian rhythms serve as zeitgeber, stimuli that pull and keep circadian rhythms in synchrony. PSI thereby functions to pull and keep circadian rhythms in synchrony, and as a result reduces anxiety and increases psychological well-being.

Periodic inactivity is the single commonality among a variety of highly effective growth and therapy techniques including progressive relaxation, biofeedback training, autogenic therapy, self-hypnosis, meditation, and yoga. However, since PSI incorporates only the essentials of these techniques, and does away with all the unnecessary and cumbersome extras associated with them, it is in fact more effective and efficient.

Both treatments continued for 6 months, after which subjects were posttested and debriefed. Twenty TM and 24 PSI subjects reported for posttesting. To this sample were added 2 TM and 3 PSI subjects who were not available for 6-month posttesting but who did take an abbreviated posttest after 3½ months. These subjects were included to increase sample size, since there is strong evidence that 6 months of TM is no more therapeutic than 3½ months (Smith, 1975a).

Outcome and Continuation Measures

Trait anxiety was selected as the main outcome variable, specifically pretest-posttest difference scores on the Anxiety Trait (A-Trait) scale of the State-Trait Anxiety Inventory (STAI; Spielberger, Gorsuch, & Lushene, 1970). Anxiety was selected because it is the most widely studied trait in meditation research (Smith,

1975b). Although proponents of TM claim that their technique has a desirable impact on other variables, notably self-esteem, psychosis, self-actualization, creativity, and even intelligence (Glueck & Stroebel, 1975; Kanellakos & Ferguson, 1973; Orme-Johnson, Domash, & Farrow, 1974), the supporting evidence is scanty. Indeed, TM subjects in the present study displayed no change on any of these variables (Smith, 1975a).

In addition, at posttest subjects were asked to estimate how often they had practiced each month throughout the project. Subjects were considered to have continued practicing if they practiced at least once during the last month.

Demographic and Pretest Personality Measures

Before the onset of the project, each subject was given the STAI A-Trait scale, the Epstein-Fenz Manifest Anxiety Scale (Fenz & Epstein, 1965), the 16 Personality Factor Questionnaire Forms A and B (16 PF; Cattell, Eber & Tatsuoka, 1970), the IPAT Neuroticism Scale Questionnaire (Scheier & Cattell, 1961), the Tennessee Self-Concept Scale (Fitts, 1965), and the Marlowe-Crowne Social Desirability Scale (Crowne & Marlowe, 1964). The Epstein-Fenz test was scored for symptoms of autonomic arousal and symptoms of striated muscle tension. The three Cattell tests were pooled to increase factor reliability and were scored for the 16 primary source traits. On the Tennessee scale, the Total Positive, Psychosis, Personality Disorder, Personality Integration, Defensive Positive, and Self-criticism scales were used. In addition subjects indicated their sex and age and stated if they had at any time prior to the project considered psychotherapy or meditation and yoga. In sum, outcome and continuation were correlated with 30 variables.

Results

Tables 1 and 2 show the correlations of demographic and pretest personality variables with outcome and continuation for TM and PSI subjects. For TM subjects, outcome correlated significantly ($r \geq .396$, $p \leq .047$) with (ranked in order of significance): not having considered psychotherapy prior to the onset of the project, Sizothymia (16 PF Factor A), Autia (Factor M), anxiety (STAI A-Trait), Weaker Superego Strength (Factor G), and lack of Personality Integration.

Continuation with TM correlated significantly ($r \geq .397$, $p \leq .034$) with a low degree of Psychoticism and a high degree of Self-criticism, as well as with having considered psychotherapy prior to the onset of the project.

For PSI the results were quite different. Outcome correlated significantly ($r \geq .462$, $p \leq .027$) with Shrewdness (Factor N). Con-

tinuation correlated significantly ($r \geq .338$, $p \leq .042$) with Alaxia (Factor L), Shrewdness (Factor N), Desurgency (Factor F), Untroubled Adequacy (Factor O), High Strength of Self-sentiment (Factor Q_s), and Ego Strength (Factor C).

Discussion

One must be extremely cautious when drawing conclusions from research involving many variables and few subjects. For this reason I chose to give particular credence only to those variables that correlated most highly with outcome and continuation and have in previous research displayed greatest validity, reliability, and immunity to the effects of motivational distortion.

An intriguing picture emerges of those individuals who continue with TM and display the greatest reduction in trait anxiety. Not only are they anxious, but they score high on 16 PF Factors Sizothymia and Autia. Cattell and his colleagues (Cattell, 1957; Cattell et al., 1970) describe Sizothmic individuals as "reserved, detached, critical, cool, aloof," and "stiff." Emotionally, they are "flat" or "cautious." They tend to be critical, precise, and skeptical, and like working alone with things or words rather than with people. In interpreting this factor, Cattell (1957) hypothesizes that it reflects a "steadiness in purpose and a high level of interest in symbolic and subjective activity...a secondary result of blocking of easy interaction with the changing external world" (p. 180). In light of the apparent introversion of those who benefit from TM, it is not surprising that they tend not to have considered psychotherapy as a treatment option.

Those who benefit from TM also score high on Autia. These individuals tend to be unconventional and interested in "art, theory, basic beliefs" and "spiritual matters." However, their most important characteristic is what Cattell variously describes as a tendency to be "imaginatively enthralled by inner creations," "charmed by works of the imagination," and "completely absorbed" in the momentum of their own thoughts, following them "wherever they lead, for their intrinsic attractiveness and with neglect of realistic

considerations." Cattell speculated that fundamental to Autia may be a capacity to disassociate and engage in "autonomous, self-absorbed relaxation."

A quite different picture emerges of those who continue with and benefit from PSI. They tend to score high on 16 PF Factor N. Such individuals, according to Cattell, tend

^d 16 Personality Factor Questionnaire (16 PF) factors were obtained by pooling scores from Forms A and B of the 16 PF with scores from the Neuroticism Scale Questionnaire.

^e This and the following variables were taken from the Tennessee Self-Concept Scale.

to have "exact calculating" minds and tend to be emotionally detached and disciplined, ambitious, and esthetically fastidious. They tend not to be gregarious or to get "warmly emotionally involved" with others.

My hypothesis that the TM dropout is disturbed, anxious, withdrawn, and somewhat lacking in self-criticism appears to be supported. Although only three dropouts reported

for posttesting, they had extremely high Psychoticism scores. Fitts (1965) reports the "normal limits" on Psychoticism to be from 34 to 54 and the average score of hospitalized psychotics to be 62. The average Psychoticism score of the TM dropout was 63 ($SD = 4.58$), whereas the average score of those who continued was 48.74 ($SD = 6.46$). In addition, the dropouts scored lower in Self-criticism.

* Keyed so that 1 = did not practice at least once during the last month of the project, 2 = did practice at least once during the last month of the project.

Again, a somewhat different picture emerges of those who stop PSI. Consistent with what was predicted, they score higher on 16 PF factors related to anxiety (Factors L, O, Q₃, and C). However, they do not score higher on Psychoticism or lower on Self-criticism. Tentatively, they appear to be suspecting and are prone to dwell on frustrations (Factor L), as well as being a bit naive and gregarious (Factors N and F).

Examining the overall pattern of these results, it appears that there is virtually *no* overlap between the variables correlated with continuation and outcome for TM and for PSI. Yet I had hypothesized that if the same therapeutic processes were operating in the two treatments, they should work for the same types of individuals. I propose that a key to interpreting this inconsistency can be found in the possible interaction between treatment rationale and treatment outcome.

The rationale given for a treatment is fast emerging as a variable that can mediate attention placebo and possibly actual treatment effects (Borkovec & Nau, 1972; McReynolds, Barnes, Brooks, & Rehagen, 1973; Rosen, 1975, 1976). A treatment with a rationale that lacks credibility can be less effective than a treatment with a credible rationale. A rationale that imparts the expectation that a set of procedures is not therapeutic, or does not constitute a treatment, can reduce the effectiveness of those procedures. In addition, different rationales might render treatments appealing, credible, and as a result, effective for different types of individuals. For example, Fish (1973) described a case in which a patient from the hippie counterculture responded to systematic desensitization when it was presented as a consciousness-raising technique, whereas an engineer responded to the same technique when it was explained in terms of reciprocal inhibition.

Following what is common procedure in outcome research using attention placebo controls, highly credible but *different* rationales were given for TM and PSI. These rationales may have rendered the treatments credible, appealing, and effective for different types of individuals. The TM rationale, a religious-philosophical system from Hindu Vedantic tradition, can be summarized briefly:¹

The TM technique involves passively and continuously attending to a meaningless thought or word called a mantra. As this thought repeats in meditation, it is experienced at progressively earlier phases in its development as increasingly subtle, fine, and charming. This process is similar to following bubbles arising in an ocean to their source in the ocean bed.

As one attends to the mantra, distracting thoughts, images, and feelings spontaneously emerge. These are treated with detached acceptance; one simply favors the mantra as soon as he or she recognizes that attention has wandered. Such distractions are normal and indicate that stress is being released.

As a thought is experienced at developmentally earlier stages, relaxation increases, which, in turn, dissolves neurological knots of tension. One's mind becomes increasingly still, like a rippleless pond or the depths of an ocean. One approaches the source of thought, the eternal and absolute field of transcendental being, creative intelligence. All aspects of life are thereby enriched and improved.

It takes little imagination to see how the TM rationale may be highly appealing and credible to Sizothymic and Autic individuals. As described earlier, such people tend to be emotionally cool, steady, and detached, and might find the TM metaphors relating to stillness and detachment appealing. They tend to be "charmed" by "inner creations," a characteristic that aptly summarizes the gist

¹ The specific content of the rationale given in TM lectures and instruction is not available to the non-TM researcher. However, after interviewing two TM instructors and 15 practitioners, I concluded that much of the rationale is similar to accounts published in the popular press by TM instructors and advocates Maharishi Mahesh Yogi (1968) and Bloomfield, Cain, and Jaffe (1975). The rationale presented in this article is derived from the accounts of Maharishi and Bloomfield et al.

It should be noted that the TM program is shrouded with considerable secrecy. Not only are the specific content of lectures and instruction unavailable to the outside researcher, but TM practitioners are urged not to describe their technique or training to others. If psychologists wish to learn TM, they are asked to promise not to divulge the technique. Secrecy tends to be reinforced by the requirement that TM research proposals must first be approved by the TM organization. In my opinion, these restrictions pose serious ethical problems for the TM researcher. As exemplified in the present study, such secrecy limits the extent to which procedural components of the TM program can be isolated and investigated. At least one study on TM has been prematurely terminated partly because of the ethical difficulties associated with secrecy (White, 1976).

of the claimed TM process. And they tend to be unconventional and interested in art, theory, basic beliefs, and spiritual matters. The TM philosophy is blatantly spiritual and relies heavily on visual "artistic" metaphor.

In contrast to the TM rationale, the PSI rationale was highly intricate and mechanistic. The person who benefits from PSI was described as "shrewd, astute, exacting, calculating, ambitious," and having complex tastes. Such a person might well find the scientific-sounding precision and ambitious complexity of the PSI rationale highly credible and appealing.

Another interpretation of these findings is that the treatment processes basic to TM and PSI are in fact different and are effective for different types of individuals. Indeed, the act of meditation has frequently been claimed to have therapeutic properties (Smith, 1975b), and Pratap (1972) argues that sitting erect with eyes closed may in itself be therapeutic. However, if sitting and meditation are equally therapeutic for different individuals, then one would expect more people to benefit from TM than from PSI, since TM is done in a seated position. This was clearly not the case. The most direct way out of this inconsistency is to make the somewhat awkward assumption that something in TM, perhaps some undisclosed aspect of the TM rationale, suppresses the therapeutic impact of erect sitting.

However they may be interpreted, the findings of this experiment clearly show that personality characteristics are correlated with continuation and outcome in meditation. I propose that this finding underlines the importance of paying heed to questions of specificity. The trend in past research has been to speak of a global meditation response experienced to some degree by all meditators, with the same overall desirable effect. Meditation is quite likely a heterogeneous phenomenon, producing effects ranging from sleep to enlightenment, and incorporating such diverse processes as insight, desensitization, and suggestion. It is time that meditation researchers examine the question of *who* experiences *what* state and trait changes with *which* technique.

Anxiety: States, Traits—Situations?

Philip C. Kendall
University of Minnesota

The present study investigated the utility of situational assessments of trait anxiety in predicting state anxiety reactions. Ninety-six male subjects pre-selected as either high or low on three measures of trait anxiety—S-R Inventory of General Trait Anxiousness (S-R GTA) Physical Danger; S-R GTA Evaluation; State-Trait Anxiety Inventory (STAI A-Trait) Anxiety Trait scale—were exposed to two experimentally induced stresses (a physical danger stress and an evaluation stress). Results indicated that the STAI A-Trait and the S-R GTA Evaluation measures correlated significantly higher with each other than either did with the S-R GTA Physical Danger measure and that both stresses produced a significant increase in state anxiety. In addition, the triple interaction of type of stress, trait level, and trait measure was, as predicted, significant. This finding indicated that high-trait-anxious subjects responded with greater state reactions when the trait measure corresponded with the type of stress. The results are discussed as support for the interaction model of anxiety and for the need to measure situational components of trait anxiety.

The state-trait model of anxiety (Spielberger, 1972) is based on the conceptual framework of transitory anxiety states (A-State) and relatively stable predispositions or traits (A-Trait). The task of state-trait researchers, according to Spielberger (1972), is to "describe and specify the characteristics of stressor stimuli that evoke differential levels of A-State in persons who differ in A-Trait" (p. 39).

The central notion of the state-trait model is that persons high in A-Trait have a greater tendency to perceive situations as dangerous or threatening than persons who are low in A-Trait, and thus they are expected to respond to threatening situations with state anxiety

elevations of greater intensity. Essentially, Spielberger views trait anxiety as the measure of anxiety proneness from which predictions of state reactions can be made.

The interaction model of anxiety (Endler, 1975) was basically derived from the rationale that had been used to develop the original S-R Inventory of Anxiousness (Endler, Hunt, & Rosenstein, 1962) and its revisions (Endler & Okada, 1975). The major point that Endler and his colleagues have made is that an appropriate assessment of anxiety must consider all sources of variability: individual differences, the responses that characterize anxiety, and the *situations* that are likely to arouse anxiety.

Recently, Endler (1975) viewed the situational component as vital for predicting state anxiety reactions. He made this position clear when he stated that

if one wants to examine the interaction of physical threat and A-Trait on state anxiety, it is necessary to assess physical danger A-Trait independent of other facets of A-Trait. (p. 161)

Within the interaction model the state-trait relationship is essentially similar to that of the state-trait model with the exception that trait

The author wishes to thank A. J. Finch, Jr., John Griffin, James F. Hooke, and Donald J. Kiesler for their helpful comments on an earlier version of this manuscript. The author also expresses thanks to M. Sue Kendall for her valuable editorial consultation.

At different times during the completion of the present paper I was affiliated with Virginia Commonwealth University and the Palo Alto Veterans Administration Hospital.

anxiety is multidimensional and not unidimensional. The interaction model and the state-trait model agree that subjects high in trait anxiety will show greater state anxiety reactions under stress than will subjects low in trait anxiety, but the interaction model separates from state-trait theory in the specificity of the trait measure needed to make the differential state anxiety predictions.

The results of research using Spielberger, Gorsuch, and Lushene's (1970) State-Trait Anxiety Inventory (STAI) have indicated that individual differences in anxiety proneness (Trait Anxiety scale—A-Trait) are relatively stable and impervious to stress (Auerbach, 1973a, 1973b; Spielberger, 1972; Spielberger, Auerbach, Wadsworth, Dunn, & Taulbee, 1973), whereas the State Anxiety scale (A-State) has been found to be sensitive to various stresses (Hodges & Spielberger, 1969; Kendall, Finch, Auerbach, Hooke, & Mikulka, 1976). In addition, stressful situations of an ego-threatening nature have been found to evoke greater increases in state anxiety for high-trait-anxious than for low-trait-anxious subjects (Auerbach, 1973a; Hodges & Spielberger, 1969; O'Neil, Spielberger, & Hansen, 1969; Rappaport & Katkin, 1972) except where subjects have equal requisite skills (Kendall et al., 1976). On the other hand, in situations involving physical danger, such as threat of electric shock (Hodges & Spielberger, 1966), imminent surgery (Auerbach, Kendall, Cuttler, & Levitt, 1976; Johnson, Dabbs, & Leventhal, 1970; Spielberger et al., 1973), or films depicting physically painful accidents (Kendall et al., 1976), state anxiety reactions have been found to be unrelated to level of trait anxiety.

The S-R Inventory of General Trait Anxiousness (S-R GTA; Endler & Okada, 1975) is a self-report inventory designed to measure trait anxiety and emphasizes the importance of measuring trait anxiety in specific situations. The S-R GTA has been reported to be both a reliable measure of situational trait anxiety and one that is insensitive to momentary stress (Endler & Okada, 1975). In addition, the authors reported that the situational scales were found to be relatively independent measures.

As yet, no known study has compared the efficacy of the S-R GTA situation-specific

measures and the STAI for predicting differential state anxiety reactions. The purpose of the present study was to conduct a comparison of the models of anxiety by investigating differential state anxiety reactions in two stress situations—a physical danger stress and an evaluation stress. It was hypothesized that high-physical-danger/trait-anxious subjects (S-R GTA Physical Danger trait measure) would show greater state anxiety elevations than low-physical-danger/trait-anxious subjects for the physical danger stress, and that high-evaluation-trait (S-R GTA Evaluation trait measure) and high A-Trait (STAI) subjects would show greater state anxiety elevations than low evaluation trait and A-Trait anxious subjects for the evaluation stress. The basic hypothesis was that the trait anxiety measure corresponding to the situation would be the best predictor of the state anxiety aroused in that situation. For the S-R GTA each situational trait was expected to be predictive of that stress situation, whereas for the STAI A-Trait previous research in evaluation situations (see above), the unidimensionality of the scale (Kendall et al., 1976) and the anticipated relationship between the STAI A-Trait and S-R GTA Evaluation trait measure are indicative of accurate prediction only in evaluation stress situations. Confirmation of the hypothesis would provide support for the interaction model and would emphasize the importance of assessments of situational trait anxiety.

Method

Subjects

The subjects in the present experiment were 101 male college students selected from a pool of 173 male students (M age = 20.1) at an urban Virginia university. Only male subjects and a male experimenter participated to control for reactions characteristic of the Subject Sex \times Experimenter Sex interaction. For example, it was felt that males might protect their masculine image with a female experimenter and would subsequently report less anxiety, whereas females might seek to appear in a feminine stereotyped role with a male experimenter.

Subjects were selected based on their scores on preexperimental measures of trait anxiety. The subject selection procedure was designed to gather subject groups of high and low trait anxiety on the three preexperimental trait measures. The criterion for

Table 1
Means, Standard Deviations, and Range
of Scores of the Three Trait Measures

Trait measure	M	SD	Range
S-R GTA Physical Danger	54.09	12.19	18-75
S-R GTA Evaluation	44.34	12.32	18-73
STAI A-Trait	38.89	8.85	22-59

Note. S-R GTA = S-R Inventory of General Trait Anxiousness; STAI A-Trait = Trait Anxiety scale of the State-Trait Anxiety Inventory.

inclusion in the subject groups required scores that were in the upper 40% for the high-trait-level group and the lower 40% for the low-trait-level group. Also, to control for the other trait measures, subjects selected as high (or low) on the physical danger trait measure (S-R GTA) were not in the upper (or lower) 40% of the evaluation trait and A-Trait (STAI) scores. Likewise, subjects selected for high (or low) evaluation trait (S-R GTA) or A-Trait (STAI) groups were not in the upper (or lower) 40% of the physical danger trait scores. The means, standard deviations, and ranges of the trait scores are presented in Table 1. Three subjects were eliminated because they had previously seen the stress film, and 2 subjects were randomly eliminated to achieve an equal number of subjects in each cell. The remaining 96 subjects, 56 whites and 40 blacks, were distributed comparably across the six subject groups (one high and low group for each trait measure).

Measure of State Anxiety

State anxiety was measured using the A-State portion of the STAI. This scale consists of 20 descriptive statements that require the subjects to individually endorse on a 4-point scale (not at all, somewhat, moderately so, very much so) the degree to which each statement characterized their feelings at a particular moment in time.

Measures of Trait Anxiety

STAI A-Trait. The STAI A-Trait scale consists of 20 items that require the subjects to individually describe how they generally feel. Subjects respond to each item (e.g., "Some unimportant thought runs through my mind and bothers me") by endorsing 1, 2, 3, or 4 representing "almost never," "sometimes," "often," or "almost always."

S-R GTA. This scale consists of 15 items for each of five situations in which trait anxiety is assessed.¹ The two situations used in this study were (a) "You are in situations where you are about to or may encounter physical danger" and (b) "You are in situations where you are being evaluated by other people." The 15 items for each of these situations required responses from 1 to 5 indicating "very much" to "not at all."

Types of Stress

A physical danger and an evaluation stress were arranged to induce anxiety within an experimental laboratory setting.

Physical danger stress. This stress was a 22-minute Harvest (1970) film entitled *In the Crash*. The film presents graphic scenes of automobile crash tests at both high and low speeds. These crash tests were filmed under experimental as well as real highway circumstances. *In the Crash* has been used in previous research and has been found to be an effective stressor (Kendall et al., 1976).

Evaluation stress. The evaluation stress was a decoding task in which a word problem had to be decoded into an arithmetic solution. The problem is as follows:

$$\begin{array}{r} \text{DONALD} \\ + \text{GERALD} \\ \hline \text{ROBERT} \end{array} \quad D = 5.$$

Subjects were instructed that letters had been substituted for numbers and that the task would be to decode the letters. One part of the solution, $D = 5$, was provided. Support for the stressful nature of the task is found in previous research using similar tasks (Finch, Kendall, Montgomery, & Morris, 1975). To maximize the stress, ego-involving instructions (Spence & Spence, 1966) and a brief failure instruction (Finch et al., 1975) were included. The exact instructions and time limit are presented in the Procedure section.

Procedure

Subjects participated in groups according to one of two sequences. The sequences pertained to the order of presentation of the stress situations (physical danger then evaluation and vice versa). The two sequences were included as a counterbalanced control for order and carryover effects. The stress sequence for a given evening was decided on a restricted random basis before subjects arrived.

As subjects arrived at the laboratory room for their 7:00 p.m. appointment, they were instructed to have a seat and get comfortable. The experiment began after a 5-10 minute late grace period. Subjects were then informed by the experimenter that

I am interested in the relationship between feelings and behavior, and in order to investigate this you will be asked to fill out the "How I feel questionnaire" at certain times and later to describe some behaviors.

¹ The S-R Inventory of General Trait Anxiousness, which was published in the *Journal of Consulting and Clinical Psychology*, 1975, 43, 319-329, has only four situations. The revised version has five situations and 15 items per situation. The revised version is available from Norman S. Endler, York University, Toronto, Canada.

Following a pause, the experimenter stated that

I will be instructing you throughout your participation, so listen and you will find your job easy. If you are uncertain at any time about what you are to do, please feel free to ask.

Once everyone appeared ready, the experimenter continued by saying "What I would like you to do first is to complete the How I feel questionnaire." The STAI A-State scale was distributed with pencils, the standard instructions were read from the top of the form, and the forms were collected when all subjects had completed them.

Subjects were then instructed that they would be watching a film. They were told to "pay attention and try to get into the film, but you should not try to remember facts or details about the movie because I will not be asking questions—just watch and get the feeling." Initially, and when necessary, subjects were instructed not to talk to any of the other people during the course of the study.²

Following the film, subjects were again asked to complete the How I feel questionnaire by reporting how they had felt during the film. Subjects were next informed that the experimenter would have to rewind the film and that there were magazines available to read. The experimenter provided numerous sports and entertainment magazines (prescreened to provide an absence of stressful material, e.g., car crash pictures) and suggested that the subjects stand, stretch, relax, and look through the magazines. Subjects were reminded not to converse with each other.

When the film was rewound (approximately 10 minutes), the experimenter announced, "Now I want each of you to do something else." A pencil and a sheet of blank white paper (8½ × 11 inches) was given to each subject at his desk, and he was told to write his name across the top of the page. The experimenter then wrote the evaluation stress task on the blackboard and provided the following instructions:

This is an addition problem, only letters have been substituted for the numbers. For instance, D stands for 5. In each place where there is a D there is really a 5. Your task is to solve or decode the rest of the letters. There is a possible solution, I guarantee it. You must work on this individually, and you will be allowed a sufficient amount of time to work out the problem.

Questions were answered at this time, but no additional information was given. Finally, the experimenter provided an ego-involving comment. "This task will give me some information about your abilities that I can use to evaluate you." After 3 minutes subjects were told, "OK, everyone please stop and turn your paper over. Do not talk to your neighbors." The STAI A-State form was again distributed to the subjects while the experimenter commented:

Fill this out according to how you felt during the task. You all should have gotten the solution or at least most of it, but if you didn't, I will show you the solution at the end of tonight's projects.³

No subject solved the task in the allotted time, and all subjects should have experienced some failure and thus maximized the evaluation stress. When all STAI A-State forms were completed and collected, subjects were told that "the project is almost over, and you should sit and relax for a few minutes while I get these papers straight." After a short break subjects were asked to fill out a questionnaire not related to the present study.

Debriefing

Although the present study was rather straightforward, the debriefing explained to the subjects the actual interests of the experimenter and a brief background for the study. Subjects were also told that the experimenter had never intended to ask them to describe behavior as he had stated originally. The answer to the decoding task was presented along with a clarification of its true difficulty and an explanation that most people should not have been able to solve the problem in the allotted time. Subjects were asked not to discuss the project with other students but were told that they could talk among themselves about it. When the questions and discussion were completed, subjects were dismissed.

Only one session was held on a given evening to prevent subjects just finishing the project from passing on information to subjects just arriving. This also prevented subjects from arriving early and overhearing the debriefing session.

Results

Preexperimental Measures

Correlations of the trait measures using the original pool of 173 subjects resulted in a .38 correlation between the S-R GTA Physical Danger and Evaluation measures, a .19 correlation between the S-R GTA Physical Danger and STAI A-Trait measures, and a .52 correlation between the S-R GTA Evaluation and STAI A-Trait measures. Tests for significant differences between the correlations revealed that the S-R GTA Evaluation/STAI A-Trait correlation was significantly greater than the S-R GTA Physical Danger/STAI A-Trait

² In my previous research, induced stress tended to increase the conversion level. To prevent intersubject comparisons, subjects were instructed not to talk to each other.

³ The procedural sequence in which the evaluation stress preceded the physical danger stress was identical to that just described with the following exception: The break between stressors was covered by the experimenter stating that he had to prepare the projector for the film.

Table 2
Means and Standard Deviations of the Initial (Prestress) A-State Scores for the Subject Groups

Trait measure and level	Initial prestress A-State	
	<i>M</i>	<i>SD</i>
S-R GTA Physical Danger		
High	33.00	5.69
Low	35.62	6.48
S-R GTA Evaluation		
High	34.37	8.41
Low	30.81	7.67
STAI A-Trait		
High	37.06	7.47
Low	32.56	6.43

Note. S-R GTA = S-R Inventory of General Trait Anxiousness; STAI A-Trait = Anxiety Trait scale of the State-Trait Anxiety Inventory.

correlation, $t(167) = 4.33$, $p < .001$, and that the S-R GTA Evaluation/STAI A-Trait correlation was also significantly greater than the S-R GTA Evaluation/Physical Danger correlation, $t(167) = 1.71$, $p < .05$. These analyses indicated that the STAI A-Trait and S-R GTA Evaluation measures correlated significantly higher with each other than either did with the S-R GTA Physical Danger measure.

The means and standard deviations of the initial (prestress) A-State scores for the subject groups are presented in Table 2. An analysis of variance of the prestress scores indicated that the groups did not differ significantly, $F(5, 90) = 1.62$.

Experimental Checks

Stress. The stressful nature of the film was demonstrated by a significant t test for differences between related means of the initial and stress assessments of A-State, $t(95) = 6.08$, $p < .001$. Similarly, it was demonstrated, $t(95) = 5.50$, $p < .001$, that the evaluation task produced elevations in state anxiety. In addition, an inspection of the subjects' performance on the decoding evaluation task showed that all subjects performed at a poor level. Specifically, no one solved more than one of the letters beyond the information given.

Counterbalancing. To confirm the utility of counterbalancing the stress presentations, an analysis of variance of difference scores was conducted for subjects receiving the physical danger stress first and for those receiving it second. There was not a significant difference between the two, $F(1, 94) = 2.13$. Similarly, an analysis for the sequence of the evaluation stress revealed no significant difference, $F(1, 94) = 2.86$.

Experimental sessions. Two additional analyses were carried out to test whether there were meaningful variations in the state anxiety difference scores due to the experimental sessions. To this end, a single factor analysis of variance of A-State difference scores for the five experimental sessions was conducted. The results yielded no significant difference in physical danger or evaluation stress reactions for subjects participating in any of the sessions, $F(4, 91) = .75$, $p > .10$; $F(4, 91) = 2.45$, $p > .10$; respectively. This outcome indicated that different experimental sessions did not produce different results.

Major Hypothesis

The major hypothesis was that the change in A-State from an initial prestress period to a stress period would be greater for high-trait-level subjects than for low-trait-level subjects when the trait measure corresponded to the stressor. Thus, the A-State difference score (stress score minus initial prestress score) was the dependent measure. This hypothesis was examined via a $3 \times 2 \times 2$ analysis of variance in which type of stress was a within variable and trait level and trait measure were between variables (a three-factor mixed design with repeated measures on one factor; Winer, 1962, pp. 337-344).

The results of this analysis indicated that the main effect for trait level and the Type of Stress \times Trait Level \times Trait Measure triple interaction were significant, $F(1, 90) = 7.81$, $p < .01$, and $F(2, 90) = 9.52$, $p < .001$, respectively. The main effects of trait measure and type of stress as well as the Trait Level \times Trait Measure, Type of Stress \times Trait Level, and Type of Stress \times Trait Measure interactions were not significant. These results demonstrate that the change in state anxiety

was greater for high- than for low-trait-level subjects but was not significantly different for groups based on the trait measure or for the type of stress.

The nature of the significant triple interaction is presented in Figure 1. This illustration shows how the state anxiety difference scores varied for the trait measures, how they differed for the types of stress, and also how they varied for the high- and low-trait-level subjects. An analysis of the predicted simple effects (*t* tests) indicated that for physical danger, high-trait-level subjects were significantly greater than low-trait-level subjects on the A-State difference score under the physical danger stress, $t(30) = 3.87, p < .001$, but not significantly different under the evaluation task, $t(30) = .90, p > .10$. When high- and low-evaluation-trait subjects were compared, there was no significant difference under the physical danger stress, $t(30) = .64, p > .10$, but there was a significant difference in the evaluation task situation, $t(30) = 2.62, p < .01$, with the high-evaluation-trait subjects showing the greater A-State difference score. When high and low STAI A-Trait subjects were compared, there were no significant differences under either the physical danger stress, $t(30) = .47, p > .10$, or the evaluation stress, $t(30) = .56, p > .10$. These analyses indicated that the difference scores of the high-trait-level subjects were greater than those of the low-trait-level subjects when the situation trait measures were congruent with the stress but not when subjects were divided into high and low groups on the basis of the STAI A-Trait.

Discussion

The present study demonstrated that the STAI A-Trait and the S-R GTA Evaluation measure correlated significantly higher with each other than either did with the S-R GTA Physical Danger measure. This outcome suggests that the STAI A-Trait measure is more like the S-R GTA Evaluation measure than like the S-R GTA Physical Danger measure and appears to support previous research, which found the STAI A-Trait to be related to state anxiety in evaluation stress situations (Auerbach, 1973a; Hodges & Spiel-

Figure 1. Mean A-State (State Anxiety scale) difference scores for the two types of stress and for subjects high and low on each of the trait measures. (A-Trait = STAI Trait Anxiety scale.)

berger, 1969). Also of interest from the correlational analyses is the relatively low relationship among the measures of trait anxiety (other than the STAI A-Trait/S-R GTA Evaluation correlation). These correlations support the notion of relatively separate anxiety traits.

The efficacy of using a situational anxiety trait measure that is congruent with the stress situation in the prediction of state anxiety reactions was demonstrated in the present study. The trait measures that were viable in the present study were two *situation-specific* measures of anxiety traits, physical danger and evaluation. When the subjects were grouped according to their physical danger trait, the high-trait-level subjects showed significant differential responsiveness to the physical danger stress but not to the evaluation stress. The opposite was true when subjects were grouped on the basis of their evaluation trait scores. On the other hand, the use of a nonsituational, unidimensional trait measure (STAI A-Trait) did not predict differential state anxiety reactions. Thus, the results of

the present study support both the need for including situations in the measurement of trait anxiety and, correspondingly, the interaction model of anxiety.

The present results also support the utility of the state-trait distinction, a distinction that has already been supported in both manipulation studies and factor-analytic work (Kendall et al., 1976; Newmark, Faschingbauer, Finch, & Kendall, 1975). However, the present investigation of "states" and "traits" suggests a clarification of their relationship: Anxiety traits are predictive of anxiety states when the trait measure is congruent with the evocative situation. It appears that there is use for the inclusion of situational trait measures.

The lack of differential state anxiety responsiveness for high and low STAI A-Trait subjects under both stresses was unexpected. Since the STAI A-Trait measure correlated more with the S-R GTA Evaluation trait measure than with the physical danger measure, since previous research has reported greater state reactions for high STAI A-Trait subjects in evaluation stresses, and since the trait measure is unidimensional, the STAI A-Trait measure was viewed as indicative of a predisposition to become anxious in evaluation situations. Based on these findings, differential state reactions for high STAI A-Trait subjects were hypothesized under the evaluation stress. However, this hypothesis was not supported in the present study.

In speculating about the reasons for the insensitivity of the STAI A-Trait measure in the evaluation stress situation, the previous findings of Kendall et al. (1976) are suggestive. In that study, in which subjects were shown to have performed equally under stress and thus were considered to have had relatively equal requisite skills, high and low A-Trait subjects reacted similarly to an examination stress. In the present experiment subjects indeed performed equally; no one decoded more than one letter beyond the given information. The present inability of the STAI A-Trait to predict differential responses in an evaluation stress could be due to the similar performance of all subjects. However, this possibility is directly contradicted by the results found when the S-R GTA Evaluation measure was used

(i.e., high- and low-evaluation-trait anxious subjects *did* respond differentially).

A more parsimonious speculation about the unexpected results using the STAI A-Trait measure concerns the measure itself. That is, whereas the STAI A-Trait measure requires subjects to indicate how they generally feel, it does not specify a situation in its assessment of the anxiety trait. The ignoring of situational specificity by the STAI A-Trait measure could account for the present findings.

More importantly, the present study provides major construct validation for the Physical Danger and Evaluation portions of the S-R GTA. Since only two situations were directly investigated, the validity of the other situation traits is yet to be examined. But both the present study and the work of Endler and Okada (1975) suggest that it would be beneficial to further examine situational measures of trait anxiety.

The outcome of the present study has implications for future research in personality in general and anxiety in particular. The generality of this finding suggests that personality trait measures should be reexamined in light of the situational dimensionality of each particular trait. This reexamination would entail investigating all the situations related to the trait, organizing these situations into *classes*, and developing an instrument for the assessment of each *situational class*. Thus, instead of continuing to assess cross-situational traits or attempting to measure situation-specific responses, researchers would potentially profit from focusing on the assessment of traits in relation to *classes* of situations.

Comparison of Measures of Adaptive Behaviors in Preschool Children

Linda I. Garrity

Mendota Mental Health Institute and Waisman
Center on Mental Retardation and Human
Development, Madison, Wisconsin

Andria B. Servos

Department of Behavioral Disabilities,
University of Wisconsin

Six measures of adaptive behavior were compared to determine which tests and items best discriminate between behavior problem and nonproblem preschool children. Eleven nonproblem and 13 problem children, matched on age and IQ, were compared on the following tests: the Minnesota Child Development Inventory, the Classroom Adjustment Rating Scale, the Ottawa School Behavior Survey, the AML Behavior Rating Scale, the Teacher Rating Scale, and the Denver Developmental Screening Test. Problem children scored significantly lower than nonproblem children on all six measures. In addition, fine-motor items discriminated better than gross-motor, language, social, and behavioral items. The Minnesota Child Development Inventory items were the best discriminators, followed by items on the Ottawa School Behavior Survey and the Teacher Rating Scale.

The purpose of this study was to determine whether problem and nonproblem preschool children perform differently on six commonly used measures of adaptive behavior.

Although a large variety of screening instruments can be found in the literature, few studies exist that simultaneously compare a number of commonly used instruments on the same subject population. An exception is a study by Cowen, Dorr, and Orgel (1971) in which 367 5- and 6-year-olds were administered the AML Behavior Rating Scale, the Ottawa School Behavior Survey, the Teacher's Adjective Checklist, and the Teacher's Behavior Rating Scale. All four measures were significantly correlated, and the latter two discriminated between adjusted and maladjusted children.

There exists a paucity of data on preschool children despite the increasing emphasis on early screening and identification of problems. In addition, most studies comparing problem and nonproblem children do not match the

groups on both chronological and mental age. Because problem children often function at a lower level than nonproblem children of the same chronological age, the results of these studies are biased in favor of the nonproblem population, making it difficult to evaluate the instruments' effectiveness.

In the present study, the following six instruments were administered to determine which, if any, differentiate previously identified groups of problem and nonproblem children matched on both chronological and mental age.

The following are four teacher rating scales that investigate various behavioral dimensions: (a) the Teacher Rating Scale (TRS; Grossman & Levy, 1974), the AML Behavior Rating Scale (AML; Brownbridge & Van Vleet, 1969); (c) the Classroom Adjustment Rating Scale (CARS; Cowen, Note 1), which consists of the recently combined Teacher's Adjective Checklist (Cowen, Zax, Izzo, & Trost, 1966; Zax & Cowen, 1969) and the Teacher's Behavior Rating Scale (Cowen et al., 1966; Zax & Cowen, 1969); and (d) the Ottawa School Behavior Survey (SBS; Pimm & McClure, 1966).

This study is based on a master's thesis completed at the University of Wisconsin by the second author.

Requests for reprints should be sent to Linda I. Garrity, Mendota Mental Health Institute, 301 Troy Drive, Madison, Wisconsin 53704.

The Minnesota Child Development Inventory (MCDI; Ireton & Thwing, 1972) is a checklist filled out by the parent. The Denver Developmental Screening Test (DDST; Frankenburg & Dodds, 1967) is a performance test, relatively easy to administer by a trained examiner, in which the child is required to answer questions, draw pictures, and exhibit motor coordination. To date, no studies have compared problem and nonproblem children on these two tests. The present study compared the two groups by examining the entire tests as well as each individual subtest from the MCDI and the DDST.

It was hypothesized that the behavior problem children would evidence higher scores (suggesting greater maladjustment) on the above four teacher behavior rating scales, lower developmental age on the MCDI (total test and the eight subtests), and more delays (failure to perform a task passed by 90% of the children at the same chronological age) on the DDST (total test and four subtests).

Method

Subjects

Eleven nonproblem and 13 behavior problem children with no medical or physical problems participated in the study. Of the 11 nonproblem children, 7 were white and 4 were nonwhite (2 black and 2 Chicano). Seven of the nonproblem children were from middle-income families (5 white, 2 nonwhite), and 4 were from lower-income families (2 white, 2 nonwhite). Of the 13 problem children, 11 were white and 2 were nonwhite. Eleven (10 white and 1 black) of the problem children were from middle-income and 2 (1 white and 1 Chicano) were from lower-income families. The children were selected from nursery schools and day-care centers in the Madison, Wisconsin, area. Approximately 75 letters and consent forms were distributed to nursery school and day-care directors. It is not known how many of these were directly given to parents. Thirty parents volunteered participation and signed consent forms. Of these, 27 completed the study. Of the 27 original participants, 3 children were dropped from the study. The remaining 24 children were similar in both age and Peabody Picture Vocabulary Test IQ scores. The problem children had a mean age of 4.08 years ($SD = .60$) and a mean IQ of 110.53 ($SD = 11.30$). The nonproblem children had a mean age of 4.13 ($SD = .57$) and a mean IQ of 115.27 ($SD = 14.31$). The t for age = .21; the t for IQ = .85.

Children were assigned to problem and nonproblem groups on the basis of their performance in three structured situations: (a) while being administered the Peabody Picture Vocabulary Test in school by the ex-

aminer; (b) while being administered Borke's (1975) adaptation of Piaget and Inhelder's (1956) three mountains task, Flavell, Botkin, Fry, Wright, and Jarvis' (1968) block test, and the Coloured Progressive Matrices (Raven, 1956) in the clinic by the second author;¹ and (c) while participating in a mother-child interaction study (completing puzzles) in the clinic for another examiner. Specific precaution was taken to insure that the test items differentiated the children's cognitive capacity rather than attention span. The experimenter made certain through repeated demonstrations that the children understood each task before proceeding with the next. In each situation, the children were evaluated on a 6-point scale on each of two dimensions—degree of compliance and degree of on-task behavior. Children's actual scores range from 6 to 33 ($M = 19.5$, $SD = 9.6$), out of a possible range of 6 to 36. Three children whose scores were within $\frac{1}{2}$ standard deviation from the mean were excluded from the study; the sample thus consisted of 24 children.

The problem children represented both ends of the clinical spectrum. Based on the experimenter's observations, 5 of the 13 problem children showed evidence of withdrawn behavior and 4 exhibited negativistic and acting out behavior. The problems of the remaining 4 children were less clearly defined, but they could be labeled *anxious* and *immature* as evidenced by whining, crying, and so on.

Procedure

After receiving parental permission slips, the experimenter went to the child's school and administered the Peabody Picture Vocabulary Test. At that time the teacher was asked to fill out the four behavior rating scales: the CARS, the AML, the TRS, and the SBS, which required about a total of $\frac{1}{2}$ hour per child.

Mothers were invited to our center, whereupon each was asked to fill out the MCDI, which required about 20 minutes. Both mother and child were then taken to a testing room where the DDST, the Coloured Progressive Matrices, the three mountains task, and the blocks test were administered to the child.

Results

t tests were used to compare the scores of the problem and nonproblem children on the 18 measures (the six entire tests, the four DDST subtests, and the eight MCDI subtests). Significant differences between problem and nonproblem children were obtained on 16 of the 18 measures (see Table 1).

Problem children scored significantly lower than their nonproblem counterparts on seven

¹ These three tests, which were administered along with the Denver Developmental Screening Test in the clinic, are part of another study.

** $p < .01$.

of the eight MCDI subtests. Similar results were found on the DDST. Again, the problem children had lower developmental ages, as evidenced by a greater number of delays exhibited. The problem group had a total of 15 delays as compared to the nonproblem group, which had only 1.

A discriminant function analysis was performed using the six different tests in their entirety. The formula used to obtain a discriminant score for each subject was .058 (MCDI) + .074 (CARS) - .165 (SBS) - .091 (AML) + .088 (TRS) + 1.0 (DDST) + 15.094. Thus

Table 2
Effectiveness of the Discriminant Function Analysis

Actual	Classified as			
	Problem		Nonproblem	
	<i>n</i>	<i>p</i>	<i>n</i>	<i>p</i>
Problem	9	.69	4	.31
Nonproblem	1	.09	10	.91

to classify one subject, the scores on the six tests would be computed and multiplied by the corresponding coefficient and the constant then added. To validate the above formula, an observation was successively omitted and the data for the remaining 23 subjects were used to develop the formula to classify the 24th subject (Lachenbruch & Mickey, 1968).

The Lachenbruch and Mickey procedure was used to estimate the probability of misclassification when using the discriminant function. There were 5 errors out of 24 attempted classifications: One nonproblem child was classified as a problem child, and four problem children were classified as nonproblem. The associated probabilities are presented in Table 2.

Those items in each test that best differentiated (showed the greatest mean difference between) problem and nonproblem groups are listed in Table 3.

Discussion

This study compares the performance of problem and nonproblem children on six screen-

ing devices. The 13 problem and 11 nonproblem children in the present study were matched on both chronological and mental age, a control procedure not ordinarily used. Assignment to problem and nonproblem groups was on the basis of the children's rated performance (on compliance/noncompliance and on-task/off-task behaviors) in three structured situations. Of the 18 measures of adaptive behavior com-

pared in the study, 16 resulted in significantly poorer performance by the problem children.

The MCDI, requiring only about 20 minutes to fill out, could easily be given to a group of parents whose children are entering nursery school. In fact, all but one of the individual MCDI subtests could be used alone as an even shorter mass screening device to identify problem children. The DDST also requires about

20 minutes, but it must be administered individually by a trained examiner. The four teacher rating scales, which also differentiated problem and nonproblem children, require no more than 5 minutes to complete and can be done by a teacher or an aide. Of the above six tests, only the MCDI and the DDST span the 6-month to 6-year range; thus they would presumably be useful with children even younger than preschool age.

The discriminant function analysis indicated that problem children would be identified correctly 69% of the time and the nonproblem children 91% of the time. It should be pointed out that the problem children in this study had no medical, physical, or previously identified behavioral problems, and all were functioning in typical day-care and nursery centers. Furthermore, problem and nonproblem children were similar on IQ, and all were functioning within the average range of intelligence. It is therefore expected that the probability of correctly identifying the more extreme problem children would be substantially higher if a random sampling procedure were used.

With regard to individual items, a possible relationship between early motor development and later behavioral and emotional problems is suggested. Of the 12 MCDI items that showed the greatest mean difference between problem and nonproblem children, 10 involved motor skills. Results on the DDST support this finding: In the nonproblem group, only one child failed or was delayed on an item that 90% of children with the same chronological age passed. In contrast, there were 15 delays (7 fine motor, 5 gross motor, 2 language, 1 personal-social) in the problem group. Thus, on both tasks nonproblem children functioned at a higher developmental level on motor skills in spite of the fact that the groups were matched on both age and IQ.

A strong relationship between motor skills and behavioral and emotional problems was also found by Rider (1973), who compared groups of "normal" and "emotionally disturbed" children 6½-12½ years old on the Purdue Perceptual-Motor Survey and the Southern California Sensory Integration Tests. The emotionally disturbed children exhibited significantly more abnormal reflex responses than the

normal children. More specifically, the emotionally disturbed children scored significantly lower on 11 of the 18 Purdue Perceptual-Motor Survey subtests and on 12 of the 16 Southern California Sensory Integration subtests. This relationship between motor development and emotional problems needs further exploration. If motor skills were found to be a good indicant of emotional problems, this would be particularly useful in screening very young children. Early identification of problem children increases the opportunity for effective intervention and treatment.

There is clearly a need for screening devices designed to detect behavioral and emotional problems in young children. Further validation of the findings of the present study is needed, using a randomly selected population as well as younger children.

Effects of Controlled Background Interference on Test Performance by Right and Left Hemiplegics

Richard E. Nemec
Rehabilitation Institute of Chicago

The general and lateralized effects of background interference on verbal and perceptual-motor functioning were studied as a function of presence and lateralization of brain damage. Thirty non-brain-damaged controls and 30 right and 30 left hemiplegics were given a word-naming task and the Bender-Gestalt Test under noninterference and background interference conditions. As hypothesized, (a) brain-damaged patients had significantly greater overall interference effects than controls; and (b) laterality effects were significant, that is, verbal interference was greatest in the left-hemisphere-damaged group; perceptual interference was greatest in the right-hemisphere-damaged group. Implications for treatment programs with such patients are discussed.

The laterality hypothesis states that the left hemisphere of the brain tends to be dominant in terms of verbal functioning, whereas the right hemisphere tends to be dominant for visual, spatial, or "nonverbal functioning." This hypothesis has been the subject of a variety of studies. Many of them have upheld the hypothesis, particularly in regard to verbal functioning (Hecaen, 1962; Milner, 1967; Penfield & Roberts, 1959; Reitan, 1955; Sperry, 1965). The hypothesized function of the right hemisphere with regard to perceptual, visual, or spatial functions has not been as clearly supported and has been subject to numerous but often contradictory studies (Hanvik & Anderson, 1950; Hirshenfang, 1960; Milner, 1967; Warrington, James, & Kinsbourne, 1966).

This study was designed as a further test of the laterality hypothesis. Verbal and perceptual interference were the independent variables used to assess the effect on verbal and perceptual performance in right-hemisphere (left hemiplegics) and left-hemisphere (right hemiplegics) brain-damaged patients and non-brain-damaged controls.

The symptom of increased distractibility as a result of brain damage, resulting in the need

for limited, structured, and repetitive stimuli is commonly reported (Strauss & Lehtinen, 1947). Cantor (1966) used this symptom of distractibility to modify the Bender-Gestalt, with the dependent variable being decrement with perceptual interference. The decrement in performance was found to be highly sensitive to organic brain damage, though the variable of laterality of lesion was not controlled. Decrement as a result of interference within the verbal area has been studied (Smith, 1966) but not applied to organic-nonorganic or laterality of lesion variables per se. Thus generalized as well as lateralized effects of distractibility on performance by brain-damaged subjects would be expected.

Specifically, this study investigates the relationship of distractibility in the verbal and perceptual areas to performance on verbal and perceptual-motor tasks as a function of brain damage and laterality of lesion. Using the findings of Cantor (1967) and Strauss and Lehtinen (1947) concerning the general effects of brain damage on distractibility and the laterality literature concerning differential functioning of the left and right hemispheres, the following predictions were made:

1. Background verbal interference within the verbal mode will cause a greater decrement in the verbal performance of organics than non-

Requests for reprints should be sent to Richard E. Nemec, Rehabilitation Institute of Chicago, 345 East Superior Street, Chicago, Illinois 60611.

brain-damaged controls regardless of site of lesion.

2. Background perceptual interference in the perceptual mode will cause a greater decrement in the perceptual performance of organics than non-brain-damaged controls regardless of site of lesion.

3. Patients with lesions in the right hemisphere will show more of a decrement in the perceptual sphere with perceptual interference than patients with lesions in the left hemisphere.

4. Patients with lesions in the left hemisphere will show more of a decrement in the verbal sphere with verbal interference than patients with lesions in the right hemisphere.

5. Perceptual interference in the verbal sphere will show less of a decrement in performance than verbal interference in the verbal sphere for all groups.

6. Verbal interference in the perceptual sphere will cause less of a decrement than perceptual interference in the perceptual sphere for all groups.

Method

Subjects

The subjects in this study consisted of 90 patients involved in an active rehabilitation program in two rehabilitation hospitals. Of the 90 subjects, 60 were diagnosed by a neurologist on admission as having suffered a cardiovascular accident resulting in varying degrees of paralysis to the side of the body opposite that of the involved hemisphere. Thirty of these patients displayed primary involvement of the right hemisphere and 30 displayed primary involvement of the left hemisphere. The control group consisted of 30 patients displaying no discernable central nervous system dysfunction on neurological and psychological evaluation. The non-brain-damaged controls were all involved in an inpatient rehabilitation program, had suffered some degree of physical impairment, and were selected from an age group similar to the cardiovascular accident patients. None of the subjects were diagnosed as psychotic or severely aphasic, and those with severe perceptual problems (unable to produce a scorable Bender) were excluded from the study. Fifty-one males and 39 females participated. Mean age was 63.8 years (range = 53-72). Mean educational level was 11.2 years (range = 6-13). Age, educational level, and sexual composition were nonsignificantly different across the three groups.

Procedure

Each patient was administered the Bender-Gestalt, first using plain paper, then using Cantor's perceptual

background interference procedure. The patients were asked to copy the designs on special paper, according to Cantor's method, and the performance was transferred, via carbon paper, to a blank sheet to aid in scoring. During the verbal portion of the task, the subjects were asked to name all the animals they could within 30 sec and then repeat the task while a tape, consisting of the examiner naming tools, was presented at a constant volume (approximately 65 dB[A]). In addition, to check the possibility of cross-modal interference (i.e., verbal interference affecting perceptual performance), each patient was readministered the Bender-Gestalt under conditions of verbal background interference (tape consisting of the names of tools). To investigate the possibility of perceptual interference affecting verbal performance, each patient was asked to repeat the word-naming task while fixating a series of flashing lights. The presentations were randomized to control for any practice effect. In accordance with Cantor's technique, non-related tasks such as sections of the Wechsler Memory Scale were presented between the experimental tasks to break the patient's "set." The Bender-Gestalt tasks were coded by a colleague, so that the experimenter knew nothing of the presence or locus of brain damage. The records were scored by the examiner using Cantor's modification of the Pascal-Suttell method (scoring reliability $r = .82$). The measure of change used was Cantor's: a difference score that results from the subtraction of the standard score from the interference score, with a positive score reflecting decrement in performance.

For the verbal task, a difference score reflecting the difference between the initial verbalizations and those occurring with interference was recorded. A positive difference score reflects a decrement, whereas a negative difference score reflects an increment.

Results

A two-way analysis of variance of the effects of verbal and perceptual interference across the three groups on the verbal (word-naming) task was performed. The significant main effect among groups indicated that the neurological groups differed significantly on decrement in verbal performance with background interference, $F(2, 87) = 13.66, p < .01$. There was a significant main effect for type of interference, $F(2, 87) = 28.91, p < .01$. Verbal interference had a greater effect than perceptual interference, as expected.

Table 1 presents the means for the difference scores of the three groups under the two conditions of interference, and Table 2 presents the results of the t tests between pairs of means. Table 2 indicates that neither perceptual nor verbal interference caused significant differential decrement in the verbal performance of the non-brain-damaged controls. As predicted,

Table 1
Verbal Difference Score Means Between Groups and Interference Mode

Neurological group	Interference mode	
	Verbal	Perceptual
Non-brain-damaged controls	.53	.63
Right	1.80	.77
Left	3.97	.80

however, verbal interference within the verbal task significantly impaired the performance of both brain-damaged groups, with the left-sided group being significantly more impaired in their performance than the right-sided group. The presentation of perceptual interference during the verbal task did not produce differences in performance among the three groups.

The results of a two-way analysis of variance on the effects of verbal and perceptual interference across the same three groups on the perceptual (Bender-Gestalt) task indicated that the neurological groups differed significantly on the variable of perceptual decrement with background interference, $F(2, 87) = 26.56$, $p < .01$. There was a significant main effect for type of interference, $F(2, 87) = 22.74$, $p < .01$. Perceptual interference had a greater effect than verbal interference. A significant interaction effect indicated that the magnitude and direction of the effects of background interference differed for different neurological groups, $F(2, 87) = 22.74$, $p < .01$.

Table 2
Summary Table of t Tests for Differences Between Means on Verbal Task

Groups compared	t
NBD (verbal) vs. NBD (perceptual)	1.62
Right (verbal) vs. right (perceptual)	3.41*
Left (verbal) vs. left (perceptual)	4.30*
NBD (verbal) vs. right (verbal)	2.74*
NBD (verbal) vs. left (verbal)	3.97*
Right (verbal) vs. left (verbal)	2.82*
NBD (perceptual) vs. right (perceptual)	.67
NBD (perceptual) vs. left (perceptual)	1.21
Right (perceptual) vs. left (perceptual)	.85

Note. NBD = non-brain-damaged controls; parentheses indicate the type of interference. $df = 58$.

* $p < .01$.

Table 3
Perceptual Difference Scores Between Groups and Interference Mode

Neurological group	Interference mode	
	Verbal	Perceptual
Non-brain-damaged controls	.57	.53
Right	2.07	20.63
Left	1.50	8.30

Table 3 presents the means of the difference scores for the three groups under the two conditions of interference. Table 4 presents the results of the t tests between pairs of means. Table 4 indicates that neither perceptual nor verbal interference caused a significant differential decrement in the perceptual performance of the non-brain-damaged controls. As predicted, perceptual interference during the perceptual performance had a significant negative effect on both brain-damaged groups, with the right-sided group doing significantly poorer than the left-sided group. The presentation of verbal interference during the perceptual task did not significantly differentiate among the performance for the three groups.

Discussion

All predictions were upheld. It has been shown that the decrement in performance in the perceptual area with perceptual interference was significantly related to brain damage

Table 4
Summary Table of t Tests for Differences Between Means on Perceptual Task

Groups compared	t
NBD (verbal) vs. NBD (perceptual)	.47
Right (verbal) vs. right (perceptual)	5.28*
Left (verbal) vs. left (perceptual)	4.39*
NBD (verbal) vs. right (verbal)	1.76
NBD (verbal) vs. left (verbal)	1.43
Right (verbal) vs. left (verbal)	1.01
NBD (perceptual) vs. right (perceptual)	6.72*
NBD (perceptual) vs. left (perceptual)	4.13*
Right (perceptual) vs. left (perceptual)	3.83*

Note. NBD = non-brain-damaged controls; parentheses indicate the type of interference. $df = 58$.

* $p < .01$.

within either hemisphere, as was verbal decrement with verbal interference. Hence, interference within either mode significantly reduced the performance of brain-damaged as compared with non-brain-damaged subjects regardless of the site of the lesion.

Interhemispheric differences within the verbal mode were in the predicted direction, with the decrement for the left-hemisphere group being significantly greater than for the right-hemisphere group. Similarly, in the perceptual mode the decrement for the right-hemisphere group was significantly greater than for the left-hemisphere group. No significant cross-modal effects were found, indicating that perceptual interference had little effect on verbal performance, nor did verbal interference significantly affect perceptual performance.

Relating the results specifically to the laterality hypothesis and the nonlocalization theory, the results clearly support both views. Strauss and Lehtinen (1948) hypothesized that the effects of brain damage tend to be general and diffuse and tend to be related more to the dis-inhibiting effect of brain damage on the lower centers of the brain, which are related specifically to distractibility. This view was given support in both the verbal and perceptual areas tested. It was shown that for the sample tested, brain damage on either side caused a greater decrement in verbal functioning with verbal interference and in perceptual functioning with perceptual interference than for the non-brain-damaged controls. There were, however, findings that did argue for the laterality hypothesis; that is, the left-hemisphere-damaged group was significantly more distractible than the right-hemisphere-damaged group on a verbal task with verbal interference and vice versa for the effects of perceptual interference on a perceptual task.

In summary, the findings generally support the laterality hypothesis, that is, left hemisphere dominant for verbal functioning and right hemisphere dominant for visual-spatial functioning. The results further indicate that brain damage has both a general and a specific effect. Distractibility increases with damage to the brain, but verbal and perceptual dis-

tractibility have a differentially greater effect on the damaged left and right hemispheres, respectively. In terms of treatment and rehabilitation, this study supports the rationale for a structured, controlled, and limited stimulation program for any patient having suffered a cardiovascular accident. An additional implication is that in setting up an ideal treatment environment, one must consider not only the level of potentially distracting environmental stimulation but also the type of stimulation with reference to the site of the lesion.

The Enigma of Androgyny: Differential Implications for Males and Females?

Warren H. Jones, Mary Ellen O'C. Chernovetz, and Robert O. Hansson
University of Tulsa

A program of studies ($N = 1,404$) tested the hypothesis that psychological androgyny (i.e., a balance of masculine and feminine characteristics) permits greater behavioral flexibility and consequently leads to better adjustment. A variety of methods were used to compare androgynous with sex-typed and opposite sex-typed individuals along several attitudinal, personality, and behavioral dimensions. Contrary to expectation a pattern of findings replicated across measures of attitudes toward women's issues, gender identification, neurosis, introversion-extraversion, locus of control, self-esteem, problems with alcohol, creativity, political awareness, confidence in one's own ability, helplessness, and sexual maturity indicated that flexibility and adjustment were generally associated with masculinity rather than androgyny for both males and females. A subsequent experiment further revealed that feminine subjects, independent of gender, would prefer to become more masculine were that possible. These results are interpreted as suggesting an alternative to Bem's theory of androgyny. Additional analyses indicated few differences between the additive and the original definitions of androgyny.

A common assertion in the feminist movement and in recent psychological theory is that traditional sex roles are confining and that new roles for women will result in more rewarding options for men as well. In this context, the present research tested a wide variety of adaptability-adjustment hypotheses, derived from androgyny theory (Bem, 1974).

In an important series of articles, Sandra Bem (1974, 1975) challenged the assumption frequently found in the literature that persons who adopt a conventional masculine or feminine role are somehow "healthier." Bem argued that internalizing a culturally imposed, "appropriate" sex role may inhibit the development of a full and satisfying behavioral repertoire. By contrast, the androgynous individual

who identifies with both desirable masculine and desirable feminine characteristics is freed from such stereotypic sex role limitations and is able to more comfortably and effectively engage in both "masculine" and "feminine" behaviors across a variety of social situations. Thus, the concept of androgyny denotes a person who is flexible, socially competent, able to respond to shifting situational demands, and more complete and actualized in the sense of developing and maximizing personal potential.

Initial validation studies using the Bem Sex-Role Inventory (BSRI; Bem, 1974) generally revealed the behavior of androgynous persons to be less stereotyped or constrained by conventional sex role standards. Given a choice of activities in which they believed they would be photographed, such persons were less likely than sex-typed individuals to prefer gender-appropriate activities, and if required to publicly perform a gender-inappropriate behavior, they experienced less discomfort (Bem & Lenney, 1976). Androgynous women were less dependent and conforming in a standard conformity experiment, and androgynous men were more likely than their sex-typed counter-

Preliminary reports of this article were presented at the meeting of the Southwestern Psychological Association, Albuquerque, New Mexico, April-May, 1976.

parts to display "feminine playfulness" with a small kitten (Bem, 1975). Masculine men were less likely to approach and play with a human baby and showed the least sympathy for the personal problems of another person. Although feminine women showed the most sympathy, they were expressively deficient with the kitten, whereas androgynous subjects were able to perform both functions adequately (Bem, Martyna, & Watson, 1976).

Bem's theory suggested a wealth of new hypotheses concerning the greater flexibility, adaptability, social competence, and psychological health of androgynous individuals, and several pertinent empirical studies using the BSRI have now been reported. A review of these studies, however, raises a number of questions regarding (a) differential patterns of results concerning the effects of androgyny for males and females, (b) the generalizability of current demonstrations of the flexibility of androgynous individuals, and (c) the validity of the BSRI.

The first issue concerns the idea that less traditional roles will be equally rewarding for both men and women. Although a few inconsistencies have been reported, the presently available evidence suggests that androgynous females are less conventional and less constrained by sex role identification than their sex-typed counterparts. For example, androgynous females as compared to feminine females have been found to be less traditional, inhibited, or restrained regarding occupational and educational objectives, marital and childbearing preferences, sexual behavior and attitudes, willingness to discuss menstrual problems, and career versus family orientations (Allgeier, 1975; Allgeier, Note 1; Kamens & Liss-Levinson, Note 2; Brooks & Birk, Note 3; Chernovetz, Hansson, & Jones, Note 4). The data for male subjects in these studies, however, are less convincing, with most studies reporting no differences, or in some instances, results contrary to expectation.

A second major issue concerns the generalizability of currently available demonstrations of the adaptability of androgynous individuals. Bem's early validation studies were creative, but they did not adequately test a range of competencies sufficient to justify the conclusion that androgynous persons are behavior-

ally and emotionally more adaptable. Indeed, much of the presently available data do not directly address the issues of mental health and social competence. Moreover, in one study, androgynous subjects yielded not only higher self-esteem and lower general maladjustment and psychosis scores but also higher scores on a neurosis scale (Nevill, Note 5). Also, the studies of investigators other than Bem contain considerable methodological variation, thereby rendering generalization difficult. For example, some studies have homogenized the subject sample, whereas others have used all available subjects. Some have failed to include opposite sex-typed subjects or males in the design, whereas others have included them, and still others have combined males and females, or opposite sex-types individuals with conventionally sex-typed individuals.

Finally, several questions concerning the validity of the BSRI as a measure of psychological androgyny have been raised. For example, low correlations between sex of subject and endorsement of specific items of the masculinity and femininity subscales (Rothman & Bryson, Note 6), possible misuse of the *t* statistic, and a possibly overlooked significant difference concerning the desirability of masculine traits for females between male and female judges in the initial scaling sample have been reported (Strahan, 1975). Furthermore, three factor analyses of BSRI responses have been reported that show contradictory results (Wakefield, Sasek, Friedman, & Bowden, 1976; Rothman & Bryson, Note 6; Gaudreau, Note 7), and the one study that attempted to replicate Bem's original scaling procedures with a new sample generally failed to do so (Edwards & Ashworth, Note 8).

Of particular concern has been the criticism of Spence and her colleagues (Spence, Helmreich, & Stapp, 1975) regarding the inability of Bem's original subtractive scoring method to detect subjects scoring low on both masculinity and femininity. The major implication is that although such persons might be androgynous as a result of their equivalent masculinity and femininity subscores, they are probably less well adjusted due to a negative self-concept reflected in such lower scores. After an empirical examination of this criticism, Bem (1977) acknowledged that on some variables the per-

formance of undifferentiated subjects (i.e., those whose masculine and feminine scores both were below the observed median) indicated a poorer sense of self-esteem than did that of the androgynous subjects (whose masculinity and femininity scores both were above the median). Such differences, she concluded, justified restricting the designation *androgynous* to persons whose masculine and feminine scores did not differ significantly, and for whom both scores were above the observed median.

In response to these considerations, we conducted a series of investigations designed to assess the implications of psychological androgyny as measured by the BSRI for individual adaptability, adjustment, and competence and to further explore the apparently inconsistent findings concerning the implications of androgyny for males and females. These objectives were pursued by testing 16 hypotheses across five areas of psychological functioning: (a) feminist ideology and gender identification, (b) personality and adjustment, (c) intellectual competence, (d) helplessness, and (e) sexual maturity and heterosexuality. In addition, the question of undifferentiated subjects was examined by comparing, on selected variables, the male and female androgynous subjects as defined by Bem's method versus the Spence et al. method.

Feminist Ideology and Gender Identification

The first major focus concerned the relationship between sex role orientation as measured with the BSRI and identification with the feminist movement—an attempt to locate the construct of androgyny in the context of contemporary and relevant social phenomena. Contrary to expectation, BSRI scores have failed to correlate with two separate measures of attitudes toward women (Zeldow, 1976; Kamens & Liss-Levinson, Note 2). It is reasonable to assume, however, that individuals, particularly females, who conceive of themselves in a less traditional manner would be more favorably disposed toward a social movement attempting redefinition of appropriate sex role behavior. Another, and perhaps less obtrusive, index of feminist orientation could be obtained from the frequency and type of gender reference used in self-descriptions, since

two common themes of the feminist movement have been consciousness raising and challenges to manifestations of sexism in the language used to describe the sexes. Thus, it was hypothesized that subjects with less conventional sex role orientations would be (a) more sympathetic to the goals and objectives of women's liberation; (b) more inclined to refer to gender in self-descriptions, particularly females; (c) but less likely to use a diminutive or denigrating form of gender reference such as girl versus woman or boy versus man.

Personality and Adjustment

A second area of inquiry involved the relationship between androgyny and other personality constructs concerned with adaptability, coping strategies, adjustment, and self-direction. The major implication of Bem's concept of sex roles is the notion that androgynous individuals are healthier and more adaptable as a consequence of their greater behavioral flexibility. Because only limited and somewhat contradictory data have been produced to date to support this assumption, five personality-adjustment dimensions were selected to assess Bem's androgyny equals mental health hypothesis including neurosis, introversion-extraversion, locus of control, self-esteem, and problem drinking.

Neurosis is generally viewed as a dispositional index reflecting tendencies toward anxiety, avoidance, moodiness, ineffective and self-defeating coping strategies, poor social skills, and a negative self-image. Within the context of neurosis, Eysenck and Rachman (1965) defined the construct *introversion-extraversion* as a continuum ranging from vulnerability to anxiety, apathy, irritability, depression, contemplation, and aloofness to hypochondriasis, sex problems, and optimism. Locus of control refers to the expectation that one's behavior will lead to desirable goals and reinforcement. Individuals might perceive the outcome of a behavioral event as under their control (internal) or beyond their control (external). Individuals who have a generalized expectancy that is external have been found to be less successful at coping with and controlling their environment, less effective at cognitive processing and academic achievement, and less

independent and self-reliant (Phares, 1976). Self-esteem denotes an evaluation of one's own adequacy and worth. Low levels of self-esteem have been related to a variety of adjustment-related variables including anxiety, unhappiness, neuroticism, drug usage and alcoholism, lack of confidence, susceptibility to external influence, and so forth (e.g., Coppersmith, 1967; Wylie, 1965). Even though the implications of problem drinking are straightforward, it is important also to note that some theories of problem drinking and alcoholism suggest the involvement of exaggerated sex role anxiety. Thus, male problem drinkers appear to derive a sense of power and masculinity from intoxication, whereas female problem drinkers gain a greater sense of feminine adequacy (e.g., McClland, Davis, Kalin, & Wanner, 1972; Wilsnack, 1973a, 1973b).

If, as we assume, androgyny implies adaptability along a variety of dimensions and in numerous settings, then it would be expected that androgynous subjects would yield a pattern of responses on these variables reflecting a strong sense of self-worth, inner-direction, social competence, and freedom from pathology. Specifically, it was predicted that androgynous individuals would be (a) less neurotic; (b) more extraverted; (c) more internal; and (d) higher in self-esteem, (e) with fewer alcohol-related problems.

Intellectual Competence

Less conventional sex role orientations have been associated with superior intellectual functioning and competence, suggesting indirect support for Bem's adaptability hypotheses, but again these differences seem more important for females than for males (Maccoby, 1966; Maccoby & Jacklin, 1974). A more direct test of the implications of androgyny for intellectual functioning might involve relevant application of intellectual capacity, for example, creative problem solving or a sophisticated level of political awareness. Creativity is defined as the production of original but appropriate solutions to a problem and has been found to correlate with a preference for cognitive complexity, independence, intuitiveness, and self-acceptance, although typically not intelligence (Butcher, 1968). Political aware-

ness has been found to predict a wide variety of important politically related behaviors and predispositions, for example, ideology, political participation and commitment, political apathy and disenchantment, and so forth (e.g., Campbell, Converse, Miller, & Stokes, 1964; Robinson, 1967).

Recent research has suggested still another related influence on the probability of successfully accomplishing one's goals in our culture, that is, an individual's self-perception of competence in endeavors requiring assertiveness, concentration, and skill preparation. One important recent study in this area found women less willing to trust their own capacities when given an opportunity to engage in either a game of skill or a game of chance (luck) to acquire a valued prize (Deaux, White, & Faris, 1975). Although this finding seems generally attributable to the dominant sex role orientation of most males and females, passivity and lack of confidence in one's own skill might be viewed as an underlying characteristic of individuals socialized as feminine, independent of gender. An analysis of such data that included the relative influence of sex and sex-type would more completely address the question of the capacity of feminine persons of either sex to acquire sufficient aspiration, assertiveness, self-preparedness, and confidence for entry into the competitive atmosphere of employment and professional endeavor.

Specific hypotheses derived from Bem's theory were that when compared to sex-typed persons, androgynous subjects would be (a) more creative, (b) more politically aware, and (c) less likely to prefer luck over skill in an effort to acquire a goal.

Helplessness

Learned helplessness is defined as a decrement or interference in instrumental responding due to inescapable and uncontrollable aversive events and has been suggested as a model of human depression (Seligman, 1975). Since the consequent behaviors of helplessness bear resemblance to the vulnerability, conformity, lack of assertiveness, and behavioral limitations attributed to sex-typed females, sex role orientation might be expected to mediate susceptibility to the helplessness effect.

More specifically, it was hypothesized that helplessness would vary as a function of the degree of femininity of the subject, with feminine females and opposite sex-typed males showing the greatest vulnerability, whereas androgynous subjects regardless of sex and sex-typed males would not become as helpless.

Sexual Maturity and Heterosexuality

One consequence commonly attributed to unconventional sex role orientation is retarded heterosexual involvement and development. Recent studies by Allgeier (1975; Allgeier, Note 1) indicate instead that androgynous females may be in fact heterosexually precocious, whereas contradictory results were reported for androgynous males. To further clarify the relationship between sex type and behaviors related to heterosexual adjustment, subjects completed an inventory requesting retrospective data concerning their adolescent sexual and dating experiences, as well as interpersonal feelings. It was hypothesized that androgynous, as compared to sex-typed subjects, would report (a) more intimate heterosexual involvement; (b) fewer heterosexually inhibiting feelings, for example, shyness; (c) greater knowledge and awareness of sex and reproduction; and (d) fewer parental restrictions in the area of sexual behavior.

Method

Subjects

Eight separate samples (total $N = 1,404$) of general psychology college students served as subjects in the several studies to be reported, in exchange for nominal course credit.

Procedure

Students in introductory psychology classes routinely completed the BSRI. Subjects were then recruited from the resulting subject pool, and each sample was independent except as indicated below.

Bem Sex-Role Inventory

The BSRI is a self-report scale designed to measure the extent of an individual's identification with desirable masculine and feminine traits (Bem, 1974). It contains 60 personality characteristics, previously scaled as being desirable traits for males (masculine items), for females

(feminine items), or desirable for both males and females (neutral items). Subjects are asked to indicate on a 7-point scale the extent to which each characteristic is "true of them." The BSRI was originally scored by calculating the t ratio of scores in response to masculine items versus responses to feminine items. In this manner, both males and females have been classified as sex typed (feminine females and masculine males), androgynous, or opposite sex typed (masculine females and feminine males).

Bem (1974) initially identified five levels of sex typing using the BSRI: feminine ($t > 2.025$, $p < .05$), near feminine ($1 < t < 2.025$), androgynous ($-1 < t < 1$), near masculine ($-2.025 < t < -1$), and masculine ($t > -2.025$, $p < .05$). For the present series of studies, three levels of classification were used: sex typed ($t > 1.0$, in the direction of the subject's sex), androgynous ($t < 1.0$, reflecting a relatively equal endorsement of masculine and feminine characteristics), and opposite sex typed ($t > 1.0$, in the direction opposite from the subject's sex). Subjects were thus classified as masculine males (MM), androgynous males (AM), feminine males (FM), feminine females (FF), androgynous females (AF), and masculine females (MF). This system of classification reflects a decision not to discard the large number of subjects who fall in the "near" sex-typed and "near" opposite-sex-typed categories. Moreover, analyses that include the entire population distribution of sex typing and not just comparisons of the more extreme cases provide a more rigorous test of the construct and would be expected to enhance the generalizability of findings.

Using this method of classification ($1 > t > -1$), Bem reported that about 50% of her samples were conventionally sex typed, 35% were androgynous, and 15% were opposite sex typed (Bem, 1975). Similarly, for the samples reported below, 51.3% of the subjects were conventionally sex typed, 34.1% were androgynous, and 14.6% were opposite sex typed, indicating the comparability of the present subjects to Bem's samples.

As previously indicated, a controversy has arisen in the literature regarding the most appropriate procedure to be used in operationalizing the construct of androgyny. Bem's subtractive technique has been criticized for its inability to detect undifferentiated subjects, who, contrary to the original formulation, appear to be deficient in self-esteem. As an alternative, Spence et al. (1975) have suggested an additive procedure in which a fourfold classification is generated based on the observed subscore medians. Thus subjects are classified as androgynous (masculine and feminine scores above the medians); sex typed or opposite sex typed (one score above, the other below the median); and undifferentiated (both scores below the median). Bem (1977) has conceded the problem that is created by including undifferentiated subjects in the androgyny category, but she prefers the use of multiple linear regression techniques as a solution.

Much of the initial appeal of the construct of androgyny resided in the simplicity of the central theme—that a balance of desirable sex-typed characteristics would have liberating effects, reducing the confinement of convention, thereby permitting interpersonal flexibility. Since the additive model appears to add the

qualifying dimension of self-esteem to the construct of androgyny and since the use of regression techniques abandons the concept of balance altogether, the original subtractive method was retained in the present series of studies as the method of classification. However, to assess the theoretical implications of the additive model, comparisons were also made between androgynous and undifferentiated subjects for feminist ideology, adjustment and personality, and intellectual competence variables.

Feminist ideology and gender identification. To test the feminism and identity hypotheses, 155 subjects completed the Women's Liberation Ideology Scale (WLIS; Goldschmidt, Gergen, Quigley, & Gergen, 1974), a 12-item scale that measures endorsement of the "feminist" orientation on several contemporary issues, for example, abortion, equal pay for equal work, and so forth. A second sample of 163 subjects completed the "I Am" test (Kuhn & McPortland, 1954), consisting of 20 sentence completion responses to the statement *I am*, from which the frequency and type of sex referents can be determined. Inclusion of a particular reference, for example, ethnic group, is considered to indicate the salience of that reference dimension to the individual respondent (Robinson & Shaver, 1969).

Personality and adjustment. Subjects ($n = 176$) completed two widely used instruments designed to assess variables theoretically related to the adjustment and social competence implications of androgyny including neurosis, extraversion-introversion (Eysenck & Eysenck, 1963), and locus of control (Rotter, 1966). Separate samples ($n_s = 168$ and 147, respectively) completed a problem with alcohol inventory (Manson, 1965) and a measure of self-esteem (Coopersmith, 1967).

Intellectual competence. The first sample listed in the above section ($n = 176$) also was instructed to list as many current United States senators as they could within a 10-minute time limit. Questions dealing with knowledge of political figures have previously been shown to discriminate on more general dimensions of political knowledge and awareness (Robinson, 1967). A separate sample of subjects ($n = 91$) completed the Unusual Uses Test, a measure of divergent creativity (Christensen, Guilford, & Wilson, 1957). Specifically, subjects were presented with the names of six objects (e.g., an old tire, a button, etc.) and were instructed to list as many uses that the object or a part of the object might serve beyond its typical function. Responses were then scored by calculating the frequency of each suggested use for each object and by assigning the value of 1 to each totally unique response generated by each subject (i.e., not listed by any other subject) and summed across the six stimulus objects. For the luck versus skill manipulation, 191 general psychology students (92 male and 99 female) previously categorized as sex typed, androgynous, and opposite sex typed using the BSRI, were given an opportunity to volunteer to participate in one of two experiments for extra course credit. They were told that both experiments involved playing an electronic game and that although all subjects would earn minimal credit simply for participating, the total amount of credit earned would be a function of how successfully one performed the game. Success in one game, they were told, was a function of luck; the

other required skill. Subjects then chose the game they preferred to try. Their choice, to trust their skill versus luck, was the dependent variable, and the games were not actually conducted.

Learned helplessness. Subjects ($n = 156$) were tested individually, following exactly the human learned helplessness procedure of Hiroto and Seligman (1975). Masculine, androgynous, and feminine males and females were assigned randomly to three pretreatment conditions in which they were (a) given an insoluble concept learning task (helplessness group), (b) given a similar but soluble concept learning task (soluble group), or (c) were simply shown the stimulus cards without completing the task (control group). Helplessness on a subsequent problem-solving task (a series of five-letter anagrams) was then measured by latency to criterion, number correct to criterion, and trials to criterion.

Sexual maturity and heterosexuality. Subjects ($n = 136$) completed an inventory requesting retrospective self-report data concerning their adolescent sexual and dating experiences, as well as feelings and experiences that might inhibit or facilitate heterosexual activity. Item content dealt with such factors as having a steady boyfriend-girlfriend prior to age 16; kissing before age 16; sexual intercourse before age 18; learning to dance prior to age 16; popularity with the opposite sex; sensitivity to criticism; shyness; awkwardness; embarrassment; sexual curiosity; sexual worry; knowledge of sex; frequency of dating; relative importance of dating versus academic performance; parental prohibitions against dating; and parental admonitions against pregnancy.

Results

A summary of means and F tests for feminist attitudes, personality, and adjustment correlates, intellectual competence variables, and items from the sexual maturity and heterosexuality scales are presented in Table 1. Table 2 contains percentages and chi-square tests for those variables elicited in a frequency data format.

Feminist Ideology and Gender Identification

Table 1 shows that as expected, sex type was related to feminist ideology. Although there was no main effect of sex type on WLIS scores, there was a significant interaction between sex and sex type. Analysis of simple effects (t tests between sex types within sex groups) revealed differences among female subjects only, with MF indicating significantly more favorable attitudes toward women's liberation issues than either AF or FF, and a trend of AF to showing more favorable attitudes than FF ($p < .10$).

Note. Within sex groups, means with different subscripts are significantly different at the .05 level. WLIS = Women's Liberation Ideology Scale; MM = masculine males; AM = androgynous males; FM = feminine males; FF = feminine females; AF = androgynous females; and MF = masculine females.

* $p < .05$.

** $p < .01$.

Not surprisingly, all females regardless of sex type scored significantly higher than males. Thus being female, and particularly, being a less traditionally sex-typed female was related to greater endorsement of contemporary women's issues, providing construct validation for the BSRI.

Somewhat contradictory results were obtained on the I Am Test, as indicated in Table 2. As a group, females listed sex more frequently than did males, $\chi^2(1) = 4.19$, $p < .04$, suggesting greater salience of gender identification for females. Among females, however, there were no significant effects of sex type on how frequently sex was included. For males there were sex type effects, with both FM ($z = 6.01$, $p < .01$) and AM ($z = 3.44$, $p < .01$) listing gender more often than MM.

Among those subjects listing their sex, females tended to refer to themselves as a girl more frequently than males referred to them-

selves as a boy, $\chi^2(1) = 3.24$, $p < .07$. This pattern was unexpected and may suggest the internalization of at least some types of stereotypic social attitudes differentiating the sexes for females.

Despite the contradictions, these data suggest that gender is currently a more salient aspect of self-concept for females, which may reflect the recent politization of female consciousness by the feminist movement.

Personality and Adjustment

The data were analyzed in a series of 2×3 (Sex \times Sex Type) analyses of variance. Table 1 reveals significant sex differences for extraversion and problem drinking, with males scoring significantly higher on both dimensions; significant sex type differences for locus of control, neurosis, and problem drinking; and significant interactions on extraversion and self-

esteem. Analysis of simple effects indicated that with the exception of extraversion, all of the personality differences associated with sex type occurred among male subjects.

Contrary to expectation, AM showed greater externality of control, more problems with drinking, and a trend ($p < .06$) toward greater introversion than MM. Similarly, FM scored more external, more neurotic, lower in self-esteem, and had more alcohol problems when compared with MM. FM were also lower in self-esteem and more neurotic ($p < .10$) than were the AM. Contrary to prediction, these results suggest that less sex-typed males experience more rather than fewer adjustment problems. For example, the relatively dysfunctional scores for problem drinking, neurosis, and self-esteem suggest existing behavioral difficulties and a poor image of self-worth, whereas the locus of control and extraversion scores imply ongoing or future inadequacy in terms of social competence and self-direction. It should be noted that the AM scored significantly in the "less adaptable" direction on only two of these scales relative to the MM. On the other hand, in no instance did the AM score significantly "more adaptable" than the MM.

Among females, analyses of simple effects indicated that MF were more extraverted than either AF or FF. No other significant differ-

ences were observed for females, although a trend suggested that MF had more problems with alcohol than did AF ($p < .07$).

Intellectual Competence

Table 1 shows that although no main effects of sex or sex type were observed, significant interaction effects were obtained for both political awareness and creativity. AM scored lower on political awareness than did MM, and there was a similar trend ($p < .09$) for creativity. Likewise, AM scored significantly lower on creativity than the FM, whereas FM and MM did not differ in these analyses. Thus, AM clearly performed more poorly than did either sex-typed or opposite-sex-typed males on these indices of intellectual competence.

By contrast, analysis of simple effects among female subjects supported the predictions, in that both AF and MF scored higher on political awareness than did FF while not differing from one another. For creativity, the expectation was more directly confirmed, with AF yielding higher scores than FF with a similar trend ($p < .10$) in relation to MF.

Thus, the intellectual variables included in the present series of studies support Bem's theory with respect to females while directly contradicting it for males. Less traditional sex role

	Androgynous	6.00	3.86	4.11	5.00	1.92	5.44
	Feminine	4.67	2.00	1.71	3.23	1.54	3.27

Note. Data for mean latency to criteria are in seconds.

orientations appear to be associated with greater intellectual preparedness among females, whereas the pattern among males is more complex, with both sex-typed and opposite-sex-typed males manifesting greater intellectual competence than AM.

Analysis of the luck versus skill manipulation replicated the earlier finding of Deaux et al. (1975), with males more frequently than females selecting a game of skill rather than a game of chance to earn extra course credit in general psychology, $\chi^2(1) = 7.35$, $p < .01$. However, as indicated in Table 2, further analysis revealed no sex role interaction among males and only a trend ($p < .08$) among females. Nevertheless, the pattern of percentages was in the predicted direction for females, with slightly more than half of the FF selecting the game of chance rather than the skill task. On the other hand, only one third and one fifth of the AF and MF, respectively, chose to rely on chance rather than their own abilities. These data then support Deaux et al.'s earlier findings and suggest that they may be partially accounted for by the lack of confidence of the FF group. Furthermore, these findings are consistent with the literature suggesting timidity, lack of confidence, self-effacement, and lack of a sense of self-worth among sex-typed females.

Helplessness

The three dependent variables were analyzed with a series of $2 \times 3 \times 3$ (Sex \times Sex Type

\times Helplessness Condition) analyses of variance. Table 3 presents cell means for each of these variables. The analyses revealed significant sex type effects on mean latency of trials to criterion, $F(2, 138) = 3.35$, $p < .05$, and on mean errors to criterion, $F(2, 138) = 4.09$, $p < .02$. Also, a nearly significant trend emerged for the helplessness condition on mean errors to criterion, $F(2, 138) = 2.51$, $p < .08$. No other significant main effects or interaction terms were observed. Further analyses (i.e., planned-comparison t tests between sex types, within sex groups, and collapsing across helplessness conditions) revealed that the only significant differences that occurred were between AM and MM for both mean latency to criterion, $t(50) = 2.29$, $p < .03$, and mean errors to criterion, $t(50) = 2.25$, $p < .03$.

AM were slower than MM in terms of solving of anagrams, and they made more errors before reaching criterion. Thus there were no sex type differences in susceptibility to the helplessness manipulation. However, these data parallel that of political awareness and creativity, indicating apparent deficits for the AM in the areas of problem solving and acquired knowledge.

Sexual Maturity and Heterosexuality

The sexual maturity and heterosexuality data were analyzed with 2×3 (Sex \times Sex Type) analyses of variance and 2×3 (True-False \times Sex Type) chi-square tests depending on the nature of the data. As indicated in

Table 1, several Sex \times Sex Type interactions were observed while one main effect for sex typing emerged (for awkwardness). Generally, the results indicated support for the predictions that androgynous as compared to feminine females would report more intimate heterosexual involvement and fewer feelings of inhibition, but they lack confirmation for the expectation that androgynous females would indicate greater knowledge and awareness of sex and fewer parental restrictions. Planned-comparison analyses revealed that AF reported being less sensitive to criticism, less shy, less awkward, and less easily embarrassed than FF. Also, MF reported being more popular with the opposite sex than AF, with a similar trend toward being less easily embarrassed ($p < .07$), but MF also reported being more awkward than AF. Moreover, as indicated in Table 2, analogous patterns were observed among females in the frequency data, with more active adolescent sexual and related behavior being associated with less traditional sex role orientations. More MF than AF reported having a boyfriend before age 16 ($z = 2.30, p < .02$), kissing before age 16 ($z = 2.31, p < .02$), and sexual intercourse before age 18 ($z = 2.28, p < .02$). Similarly, more MF than FF reported having boyfriends before 16 ($z = 4.00, p < .01$), kissing before 16 ($z = 4.31, p < .01$), intercourse before 18 ($z = 4.20, p < .01$), and a trend in the direction of more frequently learning how to dance before 16 ($z = 1.70, p < .09$). AF also were more likely than FF to report dancing before 16 ($z = 3.20, p < .01$), kissing before age 16 ($z = 1.86, p < .06$), and sexual intercourse before 18 ($z = 1.77, p < .07$).

Sex type was a less powerful predictor of the sexual maturity and heterosexuality items for males, however. Beyond the tendency of FM to report greater sensitivity to criticism than either MM or AM, no significant differences were observed on any of these items except for the trend of AM to report being more easily embarrassed than MM ($p < .10$).

Taken together, the male data suggest differences only in terms of what might be called *interpersonal feelings*, with traditionally sex-typed males reporting fewer personal liabilities and limitations that might be expected to inhibit or constrain heterosexual involvement.

Table 4

Means for Ideal Sex Role Identification

Item	Sex type		
	Masculine	Androgynous	Feminine
Males			
Masculine	4.63	5.13	5.63
Feminine	4.25	4.11	3.98
Females			
Masculine	4.46	4.69	5.09
Feminine	4.30	4.40	4.47

Note. Higher means indicate greater desired change.

By contrast, less traditional females not only less frequently reported restraining personal characteristics (e.g., shyness), but they also reported greater heterosexual involvement. Thus, sex role identification appears to be a less powerful influence on the heterosexual behavior of males, as was found by Allgeier (1975). However, the present analyses also suggest that greater heterosexual involvement is probably a masculine characteristic independent of gender.

Ideal Sex Role Identification

The main purpose of the present series of studies was to examine attitudinal, personality, and adjustment implications of psychological androgyny. Analysis of data from the foregoing studies, however, failed to provide support for the hypotheses concerning androgynous males. One explanation is that Bem's theory is inaccurate, at least for males. A test of this possibility would be to measure the extent to which subjects would change their personality as reflected by the BSRI if that were possible. It might be the case that certain sex type groups are dissatisfied with their present behavior and inclinations. For example, if sex-typed subjects yielded significant desired change scores in the direction opposite to their gender, this would indicate the recognition of the limitations of conventional sex role expectations and the preference to be more androgynous, thereby indirectly supporting Bem's theory. It is not implied that subjects would conceptualize such change in the language of sex typing, but rather that feminine females might prefer to be more

Table 5

assertive and masculine males might desire greater tenderness.

Thus, the heterosexuality sample ($n = 136$) also completed the BSRI for a second time with a new set of instructions. For the second administration, subjects were asked to indicate the extent to which they would prefer to have more, less, or remain the same on each of the traits and qualities of the BSRI. Subjects indicated their responses on a 7-point scale, with 1 = less, 7 = more, and 4 = no change desired.

Responses to the desired change instructions for the BSRI were summed for masculine and feminine items separately for each subject, and means (by sex type) are presented in Table 4. These scores were then analyzed in a $2 \times 3 \times 2$ (Sex \times Sex Type \times Masculine vs. Feminine Items) analysis of variance with repeated measures on one factor. As indicated in Table 5, the strongest effect occurred for the type of item, with subjects indicating greater desired increases on masculine than feminine items. The Sex \times Sex Type interaction suggested that greater change was desired by opposite-sex-typed males and by sex-typed females. The Sex \times Items interaction revealed a tendency for males to desire relatively greater increases in masculinity and relatively lesser increases in femininity than did the female subjects.

Analyses of simple effects indicated that AM desired greater increases on masculine items

than did MM, $t(40) = 3.25$, $p < .01$; a similar difference between FM and MM, $t(33) = 4.41$, $p < .01$; and that FM desired greater increases on masculine traits than did AM, $t(23) = 2.20$, $p < .05$. For feminine items there were no differences among males except for a tendency of FM to desire less increase than did the MM, $t(33) = 1.83$, $p < .10$. Among female subjects, FF desired significantly greater increases on the masculine items than did AF, $t(67) = 3.53$, $p < .01$; FF showed a similar preference for increases on the masculine traits compared to MF, $t(52) = 4.78$, $p < .01$, but the difference on masculine items between AF and MF was not significant. Also there were no significant differences or trends among females on desired changes in femininity.

Thus, two important conclusions can be drawn from the ideal sex role identification data. First, both males and females indicated a strong preference for changes in the direction of masculinity as defined by the BSRI. Again, it should be noted that such desired change need not, and probably is not, conceptualized by the subjects as a desire to become more masculine. Rather, subjects indicated a strong desire to increase their capacity to behave in an instrumental fashion, that is, more assertively, more decisively, and so forth. It is interesting that the desired change in the direction of masculinity does not occur at the expense of the items measuring femininity, which might be inter-

preted as a desire to become more androgynous. However, the failure of masculine subjects to indicate the desired increases in femininity raises doubt concerning such an interpretation. With the possible exception of FM, most subjects indicated relatively little average desired change in either direction for the feminine items, suggesting a sense of satisfaction or disinterest in the areas of nurturance, emotionality, and so forth. Second, those subjects who were least masculine on the original administration of the BSRI wanted the greatest degree of increase on the masculine items. In other words, the traits that comprise the Masculinity scale of the BSRI are very important personal qualities that are highly desirable to those subjects who indicate that they do not possess them.

Androgyny and undifferentiated subjects. To assess the effect of the Spence et al. (1975) additive model, data of subjects classified as androgynous and undifferentiated were further analyzed, as indicated in Table 6. The eight variables included were selected for further analysis because of the communality among these variables and because these are the kind of data that have been used to address the issue of undifferentiated subjects. Initially, medians (combined across male and female subjects and all samples) were established for both the masculinity ($Mdn = 4.9$) and femininity ($Mdn = 5.0$) subscores. The left-hand portion of Table 6 compares those subjects originally classified as androgynous by the subtractive method who were either above both medians (high-high) and subjects who were below both medians (low-low). As can be seen, only one comparison yielded a significant difference, with low-low androgynous males manifesting significantly greater problems with alcohol than their high-high counterparts. The right-hand portion of the table reflects means and significance tests between subjects classified as androgynous versus subjects classified as undifferentiated by the additive method. It should be noted that this method not only involves partialing out high-high versus low-low androgynous subjects (with high-low and low-high subjects being assigned to sex-typed or opposite-sex-typed groups depending on gender), but it also includes high-high and low-low subjects who were originally classified as sex typed or opposite sex typed. Again, as

indicated, only one comparison produced significant differences (male undifferentiated subjects were more external) and two nonsignificant trends.

Discussion

The initial purpose of the present series of studies was to test hypotheses derived from Bem's theory of androgyny with respect to conventionality, adaptability, social competence, and adjustment. Only partial support was obtained, however, and in two important respects, data patterns systematically contradicted predictions from Bem's theory. First, the androgyny equals adaptability hypothesis seems not to hold for males. In most instances androgynous males scored in the less adaptive direction than masculine males, and frequently these differences were significant. In no case were androgynous males found to be significantly more adaptive, flexible, or competent than masculine males. Moreover, the failure of androgynous males to yield scores suggesting more adaptive or effective coping ability occurred across a wide variety of personality, adjustment, and intellectual variables, for example, locus of control, anagram solution, alcohol problems, creativity, political awareness, and so forth. It seems reasonable to conclude that these differences derive from basic psychological processes rather than the specific tasks and instruments selected for inclusion in these studies. Also, with only two exceptions, the dispositional tendencies of feminine males appeared to be even less adaptive. Again, as compared to masculine males, feminine male subjects were less secure and flexible in numerous areas such as self-esteem, problems with alcohol, sensitivity to criticism, neurotic conflict, locus of control, and so on. Only on the intellectual dimensions of creativity and political awareness did feminine males manifest socially desirable characteristics.

Thus, a pattern emerged in which masculine males can be described as more competent and confident on numerous dimensions, whereas less traditionally sex-typed males are generally more limited and restricted, less effective and more vulnerable to influence, less sure of themselves, and perhaps even less well adjusted. Not surprisingly then, when asked to indicate

their preference for change on BSRI items, feminine and androgynous males preferred to become more masculine, whereas masculine males indicated relatively little desire to change. It is also important to note that with the exception of intellectual functioning measures, the relationship between sex typing and adaptability was generally linear among males.

Second, although greater support for Bem's formulations was obtained with female subjects, in one important aspect, there was a contradiction here as well. In support of the theory are the findings that androgynous females were less conventional, more outgoing, politically aware, creative, heterosexually active, and less awkward, shy, sensitive to criticism, and so on, than were feminine females. However, the inclusion of opposite-sex-typed females, revealed that masculine females are even more feminist in their attitudes, more politically aware, more extraverted, more popular with the opposite sex, more heterosexually involved, and so on. Stated more succinctly, the more masculine in orientation, the more adaptive, competent, and secure the female subject was. Minor exceptions to this pattern were detected, such as more drinking problems and a greater sense of awkwardness for the masculine females. However, the weight of the evidence favors the above conclusion. Moreover, when given the opportunity to indicate desired change in relation to BSRI items, it was the feminine females who expressed the greatest desire to change in the direction of masculinity, with less change indicated by androgynous females and least by masculine females. As was the case with males, the less masculine the female, the more desirable increased masculinity became.

It should be noted that the precise manner in which the present findings fail to support Bem's theory is somewhat subtle. Bem initially suggested that greater adaptability of the androgynous person can best be detected cross-situationally. That is, although she did not claim that androgynous individuals would always be the most adaptable in a single situation (e.g., least conforming, most responsive to emotional needs, etc.), she did argue that when several situations are taken into consideration, they will yield the most adaptive average pattern of behavior. As regards the first part of this argument, the present data suggest that Bem is

primarily correct, in that only for creativity and political awareness among male subjects was an androgynous group found to be significantly less adaptable or competent than their sex-typed and opposite-sex-typed counterparts. However, the notion that androgynous subjects would yield the most desirable pattern of responses across several situations is directly contradicted by the present data, in that sex-typed males and opposite-sex-typed females, with very few exceptions, showed the most flexible and competent pattern of responses.

The most succinct description of the present findings is that the more adaptive, flexible, unconventional, and competent patterns of responding occurred among more masculine subjects, independent of their gender. It is possible, therefore, that the various consequences typically attributed to sex typing might be better conceptualized as a function of masculinity or the constellation of traits that the BSRI and other inventories define as masculinity. In other words, it appears that general adaptability varies as a direct linear function of a relative mix of traits dominated by such factors as assertiveness, decisiveness, and intellectuality, as opposed to nurturance, responsiveness, and emotionality. In one regard this is not surprising, since the items that comprise the masculinity subscale have the underlying commonality of being instrumental in nature, that is, the ability to effectively and efficiently accomplish objectives. Similarly, most of the variables examined involve stereotypically masculine endeavors. The social appropriateness of such tendencies for males has long been recognized in the literature of sex typing (e.g., Broverman, Broverman, Clarkson, Rosenkrantz, & Vogel, 1970; Maccoby & Jacklin, 1974). What was unanticipated was that females who completely violated societal sex role expectations appear to be happier, more competent, and more adaptive than either androgynous or sex-typed females.

Although beyond the scope of the present study, the reason for this effect probably derives from a contingent relationship between the manifestation of instrumental behaviors and the application of various social rewards such as acceptance, approval, esteem, deference, and the like. If this is so, it would explain the tendency of subjects to judge the cross-sex

behavior of males (i.e., feminine behavior) more harshly than the cross-sex behavior of females (i.e., masculine behavior; e.g., Feinman, 1974). It may also have implications for many of the sex stereotyping studies (e.g., Broverman et al., 1970), in that what is being devalued in society is perhaps not female gender but, rather, feminine behaviors.

Thus the important issue becomes not whether one has internalized the traits and behaviors appropriate to one's gender but the extent to which one has assimilated the tendencies most highly valued by society. Some theorists (e.g., Bakan, 1966) have proposed a continuum ranging from the agentic role (i.e., a dominance of instrumentality, rationality, strength, assertiveness, masculinity, etc.) to what is termed *communality* (i.e., femininity, nurturance, emotionality, expressiveness, etc.). In a society that prefers the former to the latter, it becomes reasonable to conclude that individuals high in agentic tendencies will not only be more successful within the context of such a society's values, but such persons will feel more confident due to a history of differential application of social rewards.

Conceptualizing sex role phenomena in this manner raises several intriguing questions concerning the role of both men and women who are feminine in orientation in a society that prefers and rewards masculinity; the appropriateness of currently developing clinical techniques that attempt the "androgynization" of both sex-typed males and females (e.g., Kaplan & Bean, 1976); and the long-term implications for a society that rewards agency, perhaps to the exclusion or detriment of communality.

Regarding the utility of defining androgyny according to the additive model, the present results are inconclusive. As Bem has noted, not all comparisons need to be significant to substantiate the problem of undifferentiated subjects. However, the weight of evidence in the present series of studies suggests that the majority (30 of 32) of subtractively determined androgyny means were not significantly changed by inclusion of the undifferentiated subjects.

Moreover, the Spence et al. (1975) method raises several conceptual issues that have not as yet been fully addressed in the literature. For example, the additive model tends to ob-

scure relative differences between masculinity and femininity that in the present studies were consistently related to important behaviors and dispositions for both males and females. Similarly, in some instances the additive method classifies subjects in a manner that appears to be inconsistent with the original concept of androgyny (e.g., subjects whose masculinity and femininity subscores are not significantly different but one is above and the other below the medians are classified as sex typed or opposite sex typed). Also, the additive method defines androgyny in such a way that it may be self-esteem and not androgyny that is being measured. Thus further research is needed to determine both the validity and effectiveness of the additive definition of androgyny. In particular, studies are needed that compare the subtractive and additive methods to variables that on a priori grounds would be expected to indicate sex typing or its absence.

During Training and Posttraining Effects of Live and Taped Extended Progressive Relaxation, Self-relaxation, and Electromyogram Biofeedback

Irving Beiman, Eileen Israel, and Stephen A. Johnson
University of Georgia

This study compared live and taped progressive relaxation (LR, TR), self-relaxation (SR), and electromyogram biofeedback (BF) on measures of autonomic and somatic arousal and subjective tension. Male and female respondents ($N = 40$) to an ad for therapy were evaluated in five training sessions and a posttraining assessment of self-control. During training, LR was superior to TR on reductions in physiological arousal; SR and BF were equivalent except for the superiority of SR on reductions in autonomic arousal. After training, LR was superior to the other procedures on self-control of autonomic arousal. It was concluded that LR is the treatment of choice for a variety of clinical objectives.

Although progressive relaxation training appears to be widely used in the clinical setting, research is equivocal regarding the physiological effects of the various forms of the procedure (Mathews, 1971). Using unselected, nonvolunteer female psychology students as subjects, Paul and Trimble (1970) found abbreviated live training superior to taped training on all physiological systems measured. Russell, Sipich, and Knipe (1976) also found live training superior to taped training for undergraduate females. Considering the economy and efficiency potentially afforded by taped training, it is important to determine the generalizability of these results to the clinical setting. Thus, one purpose of the present investigation was to compare the during training effects of extended live progressive relaxation to taped relaxation in a clinical population.

This investigation was supported by a small grant awarded to the first author by the Office of General Research, University of Georgia. The portions of the during training data (first three training sessions excluding biofeedback), based on a thesis by the second author, were published earlier.

Appreciation is expressed to Ernest Fruge and Lewis Humphreys, who served as therapists and to Earl Robinson, who assisted the first author by programming the computer analyses.

Requests for reprints should be sent to Irving Beiman, Department of Psychology, University of Georgia, Athens, Georgia 30602.

Other forms of relaxation training have also been recommended to therapists, including electromyogram (EMG) biofeedback (Cox, Freundlich, & Meyer, 1975; Reinking & Kohl, 1975) and self-relaxation training (Benson, 1976; Benson, Greenwood, & Klemchuk, 1975). Reinking and Kohl found EMG biofeedback superior to taped relaxation instructions for the facial muscles on reductions in forehead muscle tension in unselected psychology students. Using selected clinical subjects complaining of tension headaches, Cox et al. (1975) found live progressive relaxation training and EMG biofeedback equally superior to a medication placebo group on posttreatment resting frontalis EMG. Beary, Benson, and Klemchuk (1974), using male and female normal subjects in a one group/own control design, found a self-relaxation procedure to be effective in reducing oxygen consumption, carbon dioxide production, and respiratory rate relative to control periods.

Since a self-relaxation procedure with a therapeutic rationale has not been compared to any other of the more commonly used relaxation procedures, a second purpose of this study was to compare such a procedure to EMG biofeedback on during training reductions in physiological arousal and subjective tension. Third, since these four relaxation procedures have not previously been compared

on posttraining control of tension level, a final purpose was to evaluate their relative effectiveness in teaching clients self-control skills for the reduction of physiological arousal and subjective tension.

Method

Subjects

Participants were 19 males and 21 females chosen from respondents to local newspaper ads that solicited tense people to participate in a psychological study to alleviate their tension. On the basis of an initial clinical interview, respondents were selected who were free from acute illness, acute situational stress that could have changed during the course of therapy, and usage of psychoactive medication; had not previously received training in any of the treatment procedures to be used; were not in therapy to deal with tension; and indicated that tension was a serious problem for them. Participants were then ranked according to age ($M = 27.1$; range = 20-54) and were randomly assigned to one of four training conditions ($n = 10/\text{group}$): live progressive relaxation (LR); taped progressive relaxation (TR); self-relaxation (SR); and EMG biofeedback (BF). Female-to-male sex ratios were 5:5 for all groups with the exception of BF, which was 6:4. Each subject was scheduled for six sessions at the same time, each 3 or 4 days apart, with treatment conditions random over time of day. As a further control for physiological variations, each female received her first session at least 1 and not more than 2 weeks after the onset of her last menstrual cycle.

Apparatus

Treatment conditions were conducted in two adjoining soundproof, airconditioned, and electrically shielded experimental chambers. All physiological recordings were made on a Grass Model 7 polygraph with five 7DAC driver amplifiers. Standard preamplifiers and a Beckman electrolyte were used except as described below. Heart rate was recorded by gold-plated electrodes attached to the left wrist and leg; respiration was recorded by a thermistor placed slightly inside the nostril permitting the most air flow; integrated muscle tension was recorded from the frontalis muscle, using standard placement (Venables & Martin, 1967, p. 285) with electrodes similar to those for the electrodermal system. A Consol BSR/GSR preamplifier providing a constant current of 16 μA was used to record skin resistance level (SRL) and skin resistance response (galvanic skin response; GSR). Beckman silver-silver chloride electrodes 2 cm^2 in diameter were attached to the volar surface of the left palm and left forearm. The electrolyte was a saline solution in Unibase, as recommended by Lykken and Venables (1971). A GSR was defined as any decrease in resistance exceeding .1% of basal skin response, as recommended by Edelberg (1967). Each subject was seated in a comfortable recliner chair.

For feedback, the output from the EMG driver amplifier (integrator time constant = .2 sec) was connected to a Narco Limit Indicator (LI 300) permitting the establishment of an adjustable threshold. When the biological signal was below threshold, the LI-300 turned on a Mallory Sonalert, which provided a 1,000-cps tone. The tone volume was adjusted at the beginning of each feedback session by a variable resistance potentiometer according to the subject's preference.

Procedure

Training. For all groups, the first five sessions involved training. Upon the subject's arrival at the first session, the polygraph operator introduced himself and the therapist (in the LR condition only) and presented a general introduction to the study. The subject's particular problem with tension was then discussed, and a therapeutic rationale for the treatment was presented. The polygraph operator then attached the transducers and administered the Anxiety Differential (Husek & Alexander, 1963). This was followed by a 10-min adaptation period, during which the subject sat quietly in a semirecumbent position. The last 3 min of this period in each session served as the pretreatment basal level for all physiological measures. Training procedures were then begun (described below) with eyes closed for all subjects. The final 3 min of training served as the posttreatment assessment for all physiological measures. The posttraining Anxiety Differential was then administered, electrodes were detached, and the subject was instructed to practice his/her relaxation skills once per day. Home practice was discussed at the beginning of the second through the fifth sessions, and solutions were offered for any difficulties encountered.

Therapists in the LR and TR conditions were two male graduate students in clinical psychology. They were trained by the first author in the administration of a shortened form of the progressive relaxation training described by Bernstein and Borkovec (1973) and were experienced with the procedure. Each therapist treated one half the participants in each of the relaxation training conditions. Separate tapes were recorded by each therapist for each of the five training sessions. Taped presentation differed from live presentation only in that progression to the next muscle group was not contingent on the client's report of complete relaxation in the current muscle group. The first two sessions involved training in 16 muscle groups with tension release, the next two sessions involved 4 muscle groups with tension release, and the fifth session involved training in relaxation by recall. Thus the treatment package in this study progressed over five sessions rather than the nine sessions, as described by Bernstein and Borkovec. Training was preceded in Sessions 1, 3, and 5 by a description of tensing instructions. The actual administration of training lasted approximately 35 minutes in the first two sessions, 15 minutes in the next two, and 5 minutes in the fifth session.

BF training involved binary auditory feedback for successively lower amounts of integrated frontalis

muscle action potential. The threshold was set at the beginning of each session so that the tone was on approximately 50% of the time. When the tone had been continuously on (EMG level below threshold) for 15 sec, the threshold was lowered approximately 2.5% (1–3 μ v). If the subject did not meet the 15-sec criterion within a 2-min period, the threshold was gradually raised until the criterion was met. Thus the procedure involved gradually shaping the desired response.

In SR training the rationale emphasized the subject's potential to develop control over her/his tension level by regular practice of the relaxation response (cf. Beary et al., 1974). The client was instructed to relax as much as possible but not to go to sleep. As a control for time from pretraining to posttraining for BF, SR training also lasted 30 minutes for each training session.

Assessment of self-control. After the standard pretraining physiological assessment in the sixth session, the subject was instructed to relax as much as possible using the relaxation skills he/she had developed in the previous five training sessions. This self-control period lasted 10 minutes, with the final 3 minutes serving as the postphysiological assessment. Another Anxiety Differential and additional questionnaires (described below) were administered, electrodes were detached, and the subject was debriefed.

Assessment of trait anxiety. To assess potential changes in trait anxiety, all subjects were administered the Trait scale of the State-Trait Anxiety Inventory (Spielberger, Gorsuch, & Lushene, 1968) and the Multiple Affect Adjective Checklist (MACL; Zuckerman & Lubin, 1965) in the initial screening session and at the end of the sixth session.

Results

After confirming that there were no pre-treatment differences between groups on any measure in Session 1 (all $ps > .20$), the data for the first five training sessions were analyzed apart from the sixth session. The sixth session was conceptualized as an assessment of the subjects' ability to reduce their own arousal level when asked to do so without the concurrent aid of any therapeutic procedure. The first five sessions afforded an assessment of each procedure's specific potential for accomplishing, during training, in-session reductions in physiological and subjective tension.

The results for the five training sessions were analyzed separately: LR was compared to TR; and SR was compared to BF. This was because the duration of LR and TR was reduced systematically across sessions by virtue of the reduction from 16 muscle groups in the first session to relaxation by recall in the fifth session. The duration of training for SR and BF was held constant at 30 minutes

for each of the five sessions. This difference between the two pairs of treatments was implemented to enhance the external validity of results. Progressive relaxation training in the clinical setting is reduced in duration as training progresses (Bernstein & Borkover, 1973), whereas the duration of BF training is typically the same for each training session.

Physiological variables analyzed were electrodermal response (GSR frequency/min), heart rate (beats/min), respiration rate (cycles/min), and muscle tension (mean μ v/min). The data were quantified by trained raters, with inter-scoring reliability exceeding .99. After the reduced data were keypunched, all statistical analyses were performed using SOUPAC programs on the IBM 360 computer of the University of Georgia. A significance level of .05 was adopted for all statistical tests.

Assessment of Training Effects

Live versus taped progressive relaxation training. In-session changes for the five training sessions were evaluated by three-way analyses of variance (Treatment \times Session \times Pre-Post) on each of the five dependent variables. These analyses revealed significant pre-post main effects for respiration rate, heart rate, muscle tension, and the Anxiety Differential, $F_s(1, 18) = 10.31, 4.82, 13.38$ and 44.31 , respectively. Each of these main effects indicated that there was a significant reduction from pretraining to posttraining, although this was qualified by higher order interactions for all measures with the exception of respiration rate.

There were significant Treatment \times Pre-Post interactions for the measures of autonomic arousal—frequency of electrodermal response and heart rate, $F_s(1, 18) = 4.81$ and 9.93 , respectively. Pre-post change averaged across sessions for GSR frequency/min was -1.45 for LR and $+1.94$ for TR; and for heartbeats/min, -2.54 for LR and $+.46$ for TR. Because LR led to decreases in both GSR frequency and heart rate while TR led to increases, the significant interactions for these two measures indicate that live relaxation training was superior to taped training in accomplishing in-session autonomic relaxation.

The analyses revealed a significant Treatment \times Session \times Pre-Post interaction for muscle tension, $F(4, 72) = 3.21$. The same three-way interaction approached significance for the measure of subjective tension, the Anxiety Differential, $F(4, 72) = 2.35, p < .08$. Figure 1 depicts the mean change in muscle tension from pretraining to posttraining for each of the five training sessions. Analysis of the simple main effects for each session (Kirk, 1968, p. 222) indicated in the first session that TR was superior to LR and that in the second and third sessions that the treatments were equivalent, whereas in the fourth and fifth sessions, live training led to greater reductions in muscle tension than taped training, $F_s(1, 90) = 8.07, .11, .20, 4.65$, and 4.60 , respectively. For taped training there was a clear trend toward attenuated treatment effects as training progressed, whereas reductions in muscle tension generally increased across sessions with live training. Figure 2 presents the pre-post means in each session for the Anxiety Differential. Post hoc analyses were not performed on these data, because the interaction was not significant. Descriptively, LR led to greater mean reductions in subjective tension than TR in all but the fifth session, and LR subjects consistently attained a deeper mean level of subjective relaxation than TR subjects.

To summarize, live progressive relaxation training was superior to taped training in accomplishing in-session relaxation on three of the four physiological variables measured. Live training led to significant decreases in autonomic arousal (GSR frequency and heart

Figure 2. Pre/post Anxiety Differential means for each training session. (PRT = progressive relaxation training.)

rate) across sessions, whereas taped training resulted in increases in these two autonomic systems. Furthermore, live training was superior to taped training in reducing muscle tension, and a similar nonsignificant trend was noted for subjective tension.

EMG biofeedback versus self-relaxation training. In-session changes in the five training sessions for these two groups were evaluated by similar analyses of variance (Treatment \times Session \times Pre-Post). These analyses indicated significant pre-post reductions for heart rate, muscle tension, and the Anxiety Differential, $F_s(1, 18) = 25.26, 7.90$, and 14.03 , while the main effect for GSR approached significance, $F(1, 18) = 3.99, p < .06$.

Main effects for the two autonomic measures were qualified by significant interactions. The Treatment \times Pre-Post interaction for heart

Figure 1. Mean pre to post change in muscle tension for each training session. (PRT = progressive relaxation training.)

Figure 3. Mean pre to post change in frequency of skin resistance responses for each training session. (GSR = galvanic skin response.)

rate, $F(1, 18) = 4.29$, indicated that SR was superior to BF: Pre-post change averaged across training sessions in beats/min was -4.34 for SR and -1.91 for BF. The Treatment \times Sessions \times Pre-Post interaction for frequency of electrodermal response, $F(4, 72) = 4.69$, is presented in Figure 3. Analysis of simple main effects for the change scores in each training session indicated no differences ($p > .10$) between the two treatments in the first four sessions, $F_s(1, 90) = 2.35, .74, 2.58$, and 2.56 , respectively. In the fifth training session, BF was apparently superior to SR, $F(1, 90) = 8.37$. Closer examination, however, revealed that the atypically large increase from pretraining to posttraining for SR could have been a function of a low pretraining baseline (2.56 responses/min). This, in conjunction with a high pretraining baseline for BF (7.0 responses/min), could account for the significant interaction. Analysis of simple main effects confirmed, in Session 5, that BF had a higher pretraining baseline than SR, $F(1, 90) = 7.52$. Interpretation of the significant interaction is therefore seriously qualified by differential pretraining baselines in Session 5.

To summarize, both SR and BF led to significant reductions in somatic and subjective tension. Additionally, self-relaxation was differentially more effective than EMG biofeedback in reducing heart rate.

Assessment of Self-control

The sixth session data were analyzed by two-way analyses of variance (Treatment \times Pre-Post) to evaluate the participants' self-control over tonic physiological arousal and subjective tension. There were pre-post main effects for all voluntary response systems (cf. Paul, 1969): respiration rate, muscle tension, and the Anxiety Differential, $F_s(1, 36) = 19.99, 10.59$, and 17.78 , respectively. The analyses additionally indicated significant Treatment \times Pre-Post interactions for frequency of electrodermal response and respiration rate, $F_s(3, 36) = 3.26$ and 3.40 . Duncan's multiple-range test (Duncan, 1955), presented in Table 1, was applied to the mean change scores for each group to analyze the differential change from pretraining to posttraining. The ordered means for GSR frequency were LR = -2.98 ; TR = $+1.56$; BF = $+1.70$; SR = $+2.70$. The statistical comparison ($df = 36$) among all possible pairs of means indicated that live relaxation was superior to each of the other treatments, which were not different from each other. The ordered means for respiration rate were SR = -2.86 ; LR = -2.47 ; BF = $-.50$; TR = $-.36$. The multiple-range test indicated that neither self-relaxation nor live relaxation were different from each other, and both were superior to biofeedback and taped relaxation.

Table 1

Duncan's Multiple-Range Comparisons on Physiological Change Scores During Assessment of Self-control

Group	Obtained	SSR	Obtained	SSR	Obtained	SSR
	TR		BF		SR	
GSR frequency						
LR	4.54	> 4.04	4.68	> 4.25	5.68	> 4.36
TR			.14	4.64	1.14	4.25
BF					1.00	4.04
	LR		BF		TR	
Respiration rate						
SR	.79	1.84	2.36	> 1.94	2.50	> 1.90
LR			1.97	> 1.84	2.11	> 1.94
BF					.14	1.84

Note. SSR = shortest significant range; LR = live relaxation; TR = taped relaxation; BF = biofeedback; SR = self-relaxation; GSR = galvanic skin response. All comparisons in which the obtained value is greater than the SSR value are significant at the .05 level.

Assessment of Trait Anxiety

Treatment \times Pre-Post analyses of variance were performed on the ACL and Trait form of the STAI, which were administered prior to Session 1 and at the end of Session 6. There were significant pre-post main effects for both the Trait scale and the ACL, $F_s(1, 36) = 16.77$ and 19.00 . This indicated that all groups reported reductions in trait anxiety (Trait scale: pre = 49.66, post = 42.69; ACL: pre = 11.87, post = 8.58), with no differential change across groups.

Discussion

During Training Effects

The present results are consistent with the earlier results of Paul and Trimble (1970) and Russell et al. (1976): Live relaxation training was superior to non-response-contingent taped training in producing decreases in physiological arousal during training. Paul and Trimble's data were obtained from unselected nonvolunteer female psychology students, and abbreviated relaxation training was used (two sessions of training with 16 muscle groups). The present study extends those findings to older self-referred male and female clients. The fact that LR was superior to TR across all five training sessions on both measures of autonomic arousal is significant because the progression, in the present study, from 16 muscle groups to relaxation by recall is similar to actual clinical practice. The clinical context of this investigation and the emphasis on regular daily practice of relaxation skills further enhance the study's external validity. Thus the present results are readily generalizable to the clinical setting and contraindicate the use of taped training when reductions in physiological arousal are the clinical objective.

A preliminary report of the during training data involving a comparison of LR, TR, and SR in the same analysis (Israel & Beiman, 1977) yielded the conclusion that LR was superior to TR and SR on reductions in subjective tension, with no differential training effects for reductions in physiological arousal. These analyses involved only three training sessions with fewer subjects than the present analyses. Including the SR group in the

analyses apparently introduced a time confound because of the differential durations of the progressive and self-relaxation procedures. These factors, combined with the reduced power of the earlier analyses (Israel & Beiman, 1977), account for the differential results of the two studies. The present, more precise analyses are more appropriate for the evaluation of differential effects of live and taped modes of extended training.

Paul and Trimble (1970) speculated that the inferiority of taped training is a function of the loss of response-contingent progression through the training procedure. This hypothesis has yet to be adequately tested, although Riddick and Meyer (1973) found that taped training with response-contingent (gross motor movement) feedback was as effective as live training. Generalization of that finding to the clinical setting is limited because of the study's non-clinical situational context and subject sample, as well as the administration of only one training session. Further research, therefore, might examine the basis for the superiority of live over taped modes of training. Hypotheses of interest might include presence/absence of a therapist as well as response-contingent versus non-response-contingent progression through the procedure.

The comparison of self-relaxation and EMG biofeedback indicated that both types of training led to significant reductions in physiological arousal and subjective tension. Interestingly, SR was differentially more effective than BF in accomplishing heart rate reductions during training. This may reflect the participants' general ability to decrease heart rate in the absence of elaborate training procedures (Ray & Lamb, 1974). These data indicate that a rather elaborate biofeedback procedure involving complex and expensive equipment is no more, and possibly less, effective in producing relaxation during training than a simple self-relaxation procedure. Our BF procedure was individualized for each client by virtue of the shaping procedure used. It has been shown that the auditory feedback/eyes-closed mode of training is superior to other modes of feedback (Alexander, French, & Goodman, 1975). Yet self-relaxation was superior to feedback on one autonomic dependent variable in the present study. Previous

research on normal subjects has indicated that EMG biofeedback is superior to simple instructions to relax when EMG is the primary dependent variable (Coursey, 1975; Haynes, Moseley, & McGowan, 1975). The present results suggest that the addition of a therapeutic rationale and daily practice of relaxation skills to self-relaxation instructions yields a procedure that is at least as effective as EMG biofeedback for producing in-session relaxation in chronically anxious subjects. In the present study the superiority of self-relaxation for reducing heart rate, when considered with earlier cautions about the effectiveness of EMG biofeedback as a general relaxation training technique (Alexander, 1975; Shedivy & Kleinman, 1977), suggests that such feedback should not be used clinically to attempt to provide a general state of relaxation. For future research on how to best accomplish in-session relaxation, rather than pursue costly and questionably effective feedback as an alternative to extended progressive relaxation training in the clinical setting, it would seem preferable to investigate the potential benefits of self-relaxation training.

Posttraining Effects

This is the first investigation to report data regarding client control of tonic physiological arousal and subjective tension after relaxation training procedures have been completed. The comparison of all four training procedures on posttraining control indicated that all groups were able to significantly reduce muscle and subjective tension when asked to do so, with no differential change across groups. With respiration rate, the system under direct voluntary control (Paul, 1969), live progressive relaxation and self-relaxation training were both superior to taped progressive relaxation and biofeedback training. Only live extended progressive relaxation training led to client control over frequency of electrodermal response, a system enervated solely by the sympathetic nervous system (Sternbach, 1966). Differential patterning of control (reductions in somatic and subjective response, increases in sympathetic response) was true for all groups but live progressive relaxation. This could indicate that the other groups may have

been "actively" trying to relax. They were successful for the somatic (muscle tension, respiration rate) and subjective systems but not for the electrodermal measure of sympathetic arousal.

Considering the generally accepted operational definition of anxiety as subjective distress accompanied by sympathetic arousal (Paul, 1969), the fact that live progressive relaxation training alone led to reductions in sympathetic arousal seems particularly important. Since these clients were selected for their reported difficulties with anxiety and tension in their everyday lives, live extended progressive relaxation training would appear to be the clinical treatment of choice when client control over tonic sympathetic arousal is one of the clinical objectives.

In a separate investigation in the same laboratory, live abbreviated relaxation training was superior to self-relaxation training in analogue clinical subjects on subjective response to phobic stimuli (Beiman, Green, Webster, Rosmarin, Holliday, & Graham, Note 1). Generalization of the present investigation's results to other relaxation procedures, for example, those involving direct induction, should not be assumed and awaits empirical verification. In the interim, considering the present data as well as those of Beiman et al. (Note 1), it seems appropriate to recommend live extended progressive relaxation training as used here for the treatment of chronic or pervasive anxiety/tension.

The use of this treatment in behavioral medicine appears to have considerable promise. Since stress (involving prolonged adreno-sympathetic arousal) has been shown to produce tissue damage and contribute to an extensive and varied list of medical disorders (Selye, 1976), the use of extended relaxation training in the psychological treatment of such stress-related disorders seems particularly appropriate and has been recommended previously (Schwartz & Shapiro, 1973). The present investigation provides empirical support for such a recommendation, with the qualifications regarding specific type of training discussed above kept in mind. Extended live progressive relaxation training presented as a self-control coping skill for maladaptive tension and anxiety has also proven successful in the

nonpharmacological treatment of essential hypertension (Graham, Beiman, & Ciminero, 1977; Beiman, Graham, & Ciminero, Note 2). This and other stress-related medical disorders are potentially good targets for future outcome research on the effects of live extended progressive relaxation training.

Correlational and Factor Analysis of the Peabody Individual Achievement Test and the WISC-R

Richard L. Wikoff
University of Nebraska at Omaha

Subtest scores from the Peabody Individual Achievement Test (PIAT) and the Wechsler Intelligence Scale for Children-Revised (WISC-R) for 180 children, ages 6-17, were factor analyzed to determine the number and kinds of factors measured by the PIAT. Two factors were found when the PIAT was factored alone. Reading Recognition, Reading Comprehension, and Spelling loaded highly on a Word Recognition factor, whereas Mathematics and General Information had moderate to high loadings on a School-related Knowledge factor. When the PIAT was factored with the WISC-R subtests, a Word Recognition factor was found in addition to the three factors usually reported for the WISC-R. The School-related Knowledge factor of the PIAT was subsumed by the other factors. General Information loaded highly on the Verbal Comprehension factor, and Mathematics loaded highly on the Freedom from Distractibility factor. Implications for the interpretation of the PIAT are discussed.

The Peabody Individual Achievement Test (PIAT; Dunn & Markwardt, 1970) has gained wide acceptance and use during the past several years. It contains five subtests that are separately scored and have separate norms for both age and grade. The materials for the subtests are presented either verbally or by presenting a page of material for the subject to read. The subject responds by choosing from among four choices, which are visually presented. Raw scores are determined by the number of correct responses and can be converted to either percentile ranks or standard scores with a mean of 100 and a standard deviation of 15. In addition, there are normative tables for the total test score.

The Mathematics subtest was designed as a measure of the ability to apply mathematical concepts to the solution of problems, as opposed to a measure of computational skills or quantitative aspects of concept formation. The objective of the Reading Recognition subtest "is to measure skills in translating sequences of printed alphabetic symbols which form words into speech sounds that can be

understood by others as words" (Dunn & Markwardt, 1970, p. 19). The Reading Comprehension subtest is presented by its authors as a test of the ability to derive meaning from printed words. The Spelling subtest attempts to measure the ability to recognize correct spelling as opposed to the ability to recall the correct spelling of words. The General Information subtest is presented as a measure of general encyclopedic knowledge.

The interpretation of these five subtest scores depends on the extent to which they are measuring different factors. It is quite possible that only one factor, for example, general intelligence, is present. In this case, the best interpretations would be made from the total test score, since this score would be the most reliable. On the other hand, if the subtests are measuring five different factors, interpretations based on each separate subtest would be appropriate.

One of the most widely used intelligence tests is the Wechsler Intelligence Scale for Children-Revised (WISC-R, Wechsler, 1974). The factor structure for this test was reported by Kaufman (1975), who found three meaningful factors—(a) Verbal Comprehension, (b) Perceptual Organization, and (c) Freedom from Distractibility.

Requests for reprints should be sent to Richard L. Wikoff, Department of Psychology, University of Nebraska, Box 688, Omaha, Nebraska 68101.

The purpose of this study was to determine the number of factors being measured by the PIAT subtests and the extent to which each subtest measured the factors found. A secondary purpose was to investigate the relationship of the PIAT to the WISC-R to determine if it measures some aspect of intelligence or measures factors not found in the WISC-R.

Method

Subjects

The subjects of this study were children who were referred to me because of learning problems. Each subject's classroom achievement was below either his or her parents' or the school's expectations. Nearly all were described as hyperactive, easily distracted, having a short attention span, not completing assignments, and so on. The children ranged in age from 6 years to 17 years, with a median age of 9.87 and a mean age of 10.1. There were 123 males and 57 females. No minority children were included. All socioeconomic groups were represented, but most were from the middle class.

Procedure

Each subject was administered the WISC-R and the PIAT. Only the protocols for those subjects who had scores on 10 WISC-R subtests (excluding Digit Span and Mazes) and all five PIAT subtests were used. There were 180 subjects who met this criterion.

A principal factors solution was used to factor analyze the standard scores for the PIAT subtests. Communalities were determined by iteration, and the resulting solution was rotated using the varimax method. Rotations were performed for one, two, and three factors to determine the most appropriate structure (Gorsuch, 1974).

A second factor analysis was performed that included standard scores for 10 subtests of the WISC-R. This was done to determine if the PIAT was actually measuring achievement or if it was measuring the factors related to intelligence as found in the WISC-R (Kaufman, 1975). Varimax rotations were performed with three, four, and five factors. The four-factor solution was the most meaningful.

Results

Two factors were retained for the PIAT subtests. Reading Recognition, Reading Comprehension, and Spelling loaded highly on Factor 1. Since all three subtests require recognition of words, this factor was named *Word Recognition*. General Information and Mathematics had the highest loadings on Factor 2. Both of these subtests require a knowledge of facts acquired in school;

Table 1

Factor Structure of the Peabody Individual Achievement Test Subtests for Learning-Problem Children

Subtest	Word Recognition	School-related Knowledge	h^2
Mathematics	.33	.66	.54
Reading Recognition	.91	.37	.97
Reading Comprehension	.73	.50	.78
Spelling	.70	.40	.65
General Information	.36	.71	.63
Eigenvalue	2.09	1.49	3.58
% of h^2	58.38	41.62	100.00
% of total variance	41.80	29.80	71.60

Note. $N = 180$.

therefore, this factor was named *School-related Knowledge*. The factor loadings are presented in Table 1.

When the PIAT and WISC-R subtests were factor analyzed together, four factors were retained. The structure is presented in Table 2 along with means and standard deviations for each of the variables. The first factor had high to very high loadings for Reading Recognition, Reading Comprehension, and Spelling. This factor was clearly the Word Recognition factor from the PIAT and was obviously measuring a factor that is only barely tapped by the WISC-R subtests. The second factor had the highest loadings for Vocabulary, Comprehension, Similarities, and Information. It was labeled *Verbal Comprehension*, since it corresponds to the first factor of the WISC-R (Kaufman, 1975). The PIAT subtests had only low loadings on this factor, with the exception of General Information, which loaded highly. The third factor corresponds to the Perceptual Organization factor of the WISC-R (Kaufman, 1975). Its highest loadings were for Object Assembly, Block Design, Picture Completion, and Picture Arrangement. Mathematics and Arithmetic had the highest loadings on Factor 4. This factor appears to be similar to the Freedom from Distractibility factor of the WISC-R (Kaufman, 1975). The loadings were smaller than those reported by

Table 2

Means, Standard Deviations, and Factor Structure for the WISC-R and PIAT Subtests for Learning-Problem Children

Subtest	<i>M</i>	<i>SD</i>	Factor				<i>N</i> ²
			1: Word Recogni- tion	2: Verbal Compre- hension	3: Perceptual Organiza- tion	4: Freedom from Distracti- bility

Reading Comprehension	96.54	13.45	.75	.35	.23	.19	.77
Spelling	93.89	14.00	.77	.21	.07	.21	.69
General Information	99.94	12.45	.39	.72	.20	.22	.76
Eigenvalue			2.82	3.72	2.49	1.01	9.59
% of <i>h</i> ²			29.41	34.10	25.96	10.53	100.00
% of total variance			18.80	21.80	16.60	6.73	63.93

Note. WISC-R = Wechsler Intelligence Scale for Children-Revised; PIAT = Peabody Individual Achievement Test; *N* = 180.

Kaufman because some of the variance was rotated to other factors.

The Reading Recognition, Reading Comprehension, and Spelling subtests were all highly correlated with the Word Recognition factor. These subtests had only low correlations with the other factors, except that Reading Comprehension correlated .35 with the Verbal Comprehension factor.

The General Information subtest correlated .72 with Verbal Comprehension and .39 with Word Recognition. Correlations with the other factors were low.

The Mathematics subtest correlated the highest with the Freedom from Distractibility factor but had loadings of .38 and .34, respectively, for Word Recognition and Verbal Comprehension.

Another way of looking at the relationship of the PIAT to the WISC-R is by the correlation of the PIAT subtests with the Verbal, Performance, and Full Scale IQs of the WISC-R. These correlations are presented in Table 3.

Discussion

The structure of the PIAT subtests has not been reported previously. The results of this study indicate that there are actually only two factors rather than the five implied by the subtest organization. Factor 1 was a Word Recognition factor that included the two reading subtests and Spelling. Factor 2 was a School-related Knowledge factor that included Mathematics and General Information.

When the PIAT subtests were analyzed with the WISC-R subtests, the Word Recognition factor remained as a factor distinct from those previously reported for the WISC-R (Kaufman, 1975). The second factor was subsumed by the WISC-R factors. General Information had its highest loading on the Verbal Comprehension factor, and Mathematics loaded along with the WISC-R Arithmetic subtest on the Freedom from Distractibility factor.

The results of this analysis are not conclusive, but they suggest the possibility that the

Table 3
Correlations of PIAT Subtests with
WISC-R Verbal, Performance, and
Full Scale IQs

Subtest	Verbal	Performance	Full Scale
Mathematics	.57	.39	.57
Reading Recognition	.58	.39	.56
Reading Comprehension	.64	.43	.60
Spelling	.50	.28	.43
General Information	.78	.44	.71

Note. PIAT = Peabody Individual Achievement Test; WISC = Wechsler Intelligence Scale for Children-Revised. $N = 180$.

Freedom from Distractibility factor may actually be a numerical factor. This follows from two lines of reasoning. First, in Kaufman's (1975) analysis of the WISC-R, Arithmetic, Digit Span, and Coding (all tasks involving numbers) had moderate loadings on the Freedom from Distractibility factor. Second, the PIAT Mathematics subtest and the WISC-R Arithmetic subtest have similar loadings on this factor. However, the PIAT Mathematics subtest appears to minimize the need for concentration by presenting material visually, which the subject can refer to while solving the problem. The WISC-R Arithmetic subtest requires the subject to retain information presented orally. This problem might be investigated further by factor analyzing these tests with numerical tests whose structure is known.

Since the two reading subtests and the Spelling subtest of the PIAT are measuring the same factor, they should be interpreted together. Remedial treatment designed to

increase the scores on any one of these subtests should improve the scores on the other two as well. To increase reliability, it is suggested that these three subtests be combined and new norms presented for the new variable, Word Recognition. The other two subtests, Mathematics and General Information, can be appropriately interpreted as separate subtests. The strong relationship to Verbal Comprehension should be kept in mind when interpreting scores from the latter test. Further study is recommended to determine if persons taking this subtest might know the information sought but are unable to understand the language.

Finally, these results support the use of the PIAT as a separate test in a battery containing the WISC-R. There is at least one factor that is different from those measured by the WISC-R that provides additional information of value in developing a treatment program for helping children with learning problems. The Mathematics subtest appears to provide supplementary information, also. However, the General Information subtest correlates so highly with Verbal Comprehension that it would not be necessary to include this subtest.

Social Psychological Concepts Applied to Clinical Processes: On the Need for Precision

Ben Harris
Radford College

John H. Harvey
Vanderbilt University

This comment analyzes and critiques an attempted application of cognitive dissonance and reactance concepts to a therapy analogue. An experiment by R. M. Gordon is discussed. It is shown that key prerequisites for dissonance arousal (choice and responsibility) and for reactance induction (initial free choice) were not present. Also, self-selection of volunteers for treatment is shown to be a likely, unreported factor. Original results are reinterpreted to suggest that they were due to the frustration of some subjects' expectations rather than to arousal of reactance. A need is cited for well-informed application of experimental social psychological theories.

Recently, clinical psychologists (e.g., Brehm, 1976; Goldstein, Heller, & Sechrest, 1966) have offered theoretical analyses concerning the role of two social psychological processes (cognitive dissonance and psychological reactance) in mediating patient attitudes toward clinical treatment. Although this work has not yet had a profound impact on the practice of clinical psychology, it reflects clinicians' increased attention to social and intrapersonal processes that may affect psychotherapy theory and practice. Consistent with this emphasis, Gordon (1976) has attempted to apply cognitive dissonance and reactance theory to the important clinical variables of incentive to engage in therapy and choice of treatment. Unfortunately, he has primarily succeeded in illustrating the difficulties involved in such an endeavor. This comment criticizes the internal and external validity of Gordon's study, offers an alternative explanation for his findings, and attempts to clarify some of the conceptual issues that are raised.

Subjects

In Gordon's study, volunteers and nonvolunteers were recruited for a session of relaxation

The authors would like to thank Robert Falk for his assistance in the preparation of this comment. Thanks are also due to Robert Gordon for his gracious cooperation in answering inquiries by the first author.

training and were given a choice between two types of training (choice conditions) or were assigned to a treatment type chosen by another subject (no-choice conditions). A major challenge to the validity of Gordon's study is posed by his manner of operationalizing the concept of volunteering for treatment. In this experiment, volunteer and nonvolunteer subjects were students from a single undergraduate psychology class. On a scale of self-reported relaxation, the mean pretreatment score for all subjects was 6.8 (out of a maximum 10), suggesting that these subjects were not comparable to a clinical population. More importantly, both "volunteer" and "nonvolunteer" groups received the same amount of course credit for their participation, both groups were apparently recruited during class hours in the same week, and many volunteers and nonvolunteers received the experimental treatment in pairs (Gordon, Note 1). Thus, the act of volunteering for treatment was one with seemingly no subsequent discriminative effect on any of the subjects: The subjects made no differential sacrifice after volunteering, they received no differential incentive, and they were given no preferential choice of treatment. Thus, any experimental effect found for the factor of volunteering/nonvolunteering would be most likely due to the self-selection of subjects into volunteer and nonvolunteer groups rather than due to an actual treatment effect (i.e., dissonance arousal). In regard to this self-selection hypothesis, the male-to-female ratio for volunteer subjects was approximately 1:1, whereas it was 3:1 for nonvolunteer subjects. Also, there

was a 10% difference in the self-reported anxiety of volunteers and nonvolunteers. These differences between subjects in the volunteer and nonvolunteer conditions are consistent with Rosenthal and Rosnow's (1975, pp. 13-25, 56-59) review of self-selection effects in experimental and clinical research.

Subsequent to the selection of volunteers and nonvolunteers for relaxation training, all subjects in the Gordon study (Gordon, 1976) were exposed (in randomly constructed pairs) to the principal experimental manipulation—the "responsibility for choice" of treatment modality. This manipulation was accomplished by having one member of each pair of subjects choose between two types of relaxation training; then, both subjects were exposed to the chosen treatment. The major theoretical reason for this manipulation was that feelings of personal responsibility represent one of many necessary conditions for producing cognitive dissonance (Wicklund & Brehm, 1976, pp. 51-71). Unfortunately, the study examined here does not directly manipulate responsibility; it simply gives a choice between two therapy treatments to half of the subjects and no choice to the others. Even though perceived choice may have been varied (cf. Harvey & Harris, 1975) and may have been related to responsibility (Harvey, Harris, & Barnes, 1975), Gordon (Note 2) did not use a manipulation check to assess his subjects' actual feelings of either responsibility or choice. As a result, at least one important prerequisite for dissonance arousal may have been absent.

In evaluating Gordon's application of cognitive dissonance theory, an even more important methodological question concerns the nature of the treatment offered to subjects. In introducing the choice manipulation, Gordon argued that making an irrevocable choice between two evenly matched alternatives will produce cognitive dissonance, since the chooser's subsequent behavior is more partial to the chosen alternative than its relative attractiveness would allow. Thus, in an experimental situation similar to the one in question, Gordon would predict subjects' engaging in dissonance-reducing behavior such as selective perception of choice-related information (Ehrlich, Guttman, Schonbach, & Mills, 1957) or heightened evaluation of the selected treatment modality. Unfortunately, Gordon's methodology does not allow a test of this hypothesis, since his subjects did not choose between *evenly matched alternatives* (it was found that one treatment was preferred to the other). Thus, a second impor-

tant prerequisite for dissonance arousal was absent.

In addition to cognitive dissonance theory, Gordon invoked J. W. Brehm's (1966) theory of psychological reactance to explain his experimental results. To do this, he hypothesized that low-responsibility (no-choice) subjects will experience reactance because of their limited control over the treatment they receive. As with the dissonance-based explanation, Gordon's assumption about the involvement of a reactance process cannot be tested using his experimental method. Theoretically, reactance is induced by eliminating one or more of a person's existing free (possible) behaviors (J. W. Brehm, 1966, p. 4). In Gordon's study, the "low-responsibility" subjects were not first given choices and then restricted in their options; they were simply given a treatment selected by another subject. According to reactance theory, one would not expect this type of variation to result in either attempts to restore choice or in devaluation of the imposed treatment. Also, as with dissonance, Gordon provided no data to demonstrate *directly* the operation of a reactance process in his study.

If cognitive dissonance were aroused by Gordon's manipulation of subjects' choice, one would expect a significant main effect of this factor (high choice vs. no choice) for subjects' attitudes toward treatment. Gordon's failure to find a main effect of choice/no choice for the measure of subjects' attitudes would seem to be consistent with the above critique of the study's dissonance-related methodology.

Gordon invoked reactance theory to explain his findings for the measure of subjects' self-rated change in relaxation following treatment. He found that only volunteers with no choice of treatment failed to show a significant (post-treatment) increase in relaxation. As the above examination of the method suggests, this result is most likely *not* due to psychological reactance being aroused in the no-choice volunteers. A more likely explanation would center on the frustration experienced by the no-choice volunteers. A review of Gordon's procedure shows that volunteer subjects both expressed interest in the treatment earlier than nonvolunteers and were somewhat less relaxed ($M = 6.3$) than nonvolunteers ($M = 7.4$) before the treatment. Accordingly, they may have both desired and expected preferential treatment. For those volunteers in the no-choice condition, however, their treatment was picked by another subject who then received his or her preferred treatment simultaneously and in the same room as the no-

choice volunteer. Thus, the effect of this manipulation (less self-reported change in relaxation) can be more parsimoniously explained by attending to the relative powerlessness and frustrated expectations of the no-choice volunteer subjects.

We are not arguing here that cognitive dissonance and psychological reactance are irrelevant to theorizing about clinical variables such as attitude toward treatment and self-perceived therapeutic change. However, the elaborate previous work on these variables and theories in the area of social psychology necessitates considerable caution when making applications to clinical concerns. It is hoped that the continuing interest of clinicians in experimental social psychology (e.g., S. Brehm, 1976) will promote *well-informed* attempts to apply social psychological ideas to clinical problems and processes.

Imprecision or Dissonance? A Reply to Harris and Harvey

Robert M. Gordon
Allentown, Pennsylvania

Harris and Harvey's criticism of Gordon's research as imprecise is based on their misunderstanding of my procedures and making much ado about initial nonsignificant differences between the volunteers and the nonvolunteers. Using this to explain away the volunteer factor, they claim that the prerequisites of dissonance and reactance were not present. I suggest that the real issue is the efficacy of volunteering as an independent variable, not imprecision.

Harris and Harvey (1978) expressed a fear that clinical researchers will apply social psychological theories without due regard or understanding. As a social clinician whose predoctoral specialty was in social psychology, I don't think the problem is with sloppy cross-fertilization. Harvey and Harris (1975; Harvey, Harris, & Barnes, 1975), who have done interesting work with the choice and responsibility variables, must feel that my study (Gordon, 1976), which deals in part with the same variables, cannot also be true. Unfortunately, they appear to reconcile our supposed differences by making much ado about nonsignificant differences and misinterpreting my procedures. The only real disagreement, as I see it, is the efficacy of the volunteering variable—a theoretical issue that they avoid while focusing on perceived impreciseness.

Harris and Harvey infer that my study (Gordon, 1976) has no external validity, since the subjects used were college students rather than a clinical population—perhaps believing that dissonance and reactance are limited to college students. As evidence, they stated that the initial pretreatment mean for relaxation was 6.8. As a casual demonstration, I asked 14 of my private clients with anxiety problems the same question as was used in the Gordon study: "How relaxed are you right now?" (1 = "not at all" and 10 = "completely"). The results were very similar ($M = 6.9$, $SD = 1.0$), not surprising to anyone who makes a distinction between state and trait variables. The two are not necessarily correlated. Harris and Harvey do not feel that volunteering is an indication of motivation involving

choice, responsibility, or interest. And since they don't, they claim that the prerequisites of dissonance and reactance were not present. They claim instead that the volunteer effects are just a methodological fluke, due to initial group differences in sex and anxiety. However, sex was not found to be significantly correlated with any of the dependent measures; and the 10% difference in initial anxiety between the volunteers and nonvolunteers was also nonsignificant, $F(1, 26) = 1.84$. They also did not attempt to explain why the volunteers continued to volunteer *after* the relaxation experiment, when again there were no volunteer main-effect differences.

Harris and Harvey (1978) misinterpret the procedure as it "simply gives a choice between two therapy treatments to half of the subjects and no choice to the others" (p. 327). They conclude that both dissonance and reactance could not have existed. In reducing the actual procedure to a simple choice—no choice situation, they have eliminated the entire relationship process, which was the reason for running the subjects in pairs—to accentuate the differential feelings of responsibility and choice. Both subjects were told about two very different forms of relaxation training that were available to them and that they could have only one of them. The experimenter asked one of the subjects which form he/she would prefer and then played that tape without considering the other subject. The subject who had chosen the tape chose it for the other subject as well. The yoked other was not only unfairly denied the right to choose, but he/she also had to hear a tape chosen by the other subject. As predicted, the inferred feelings of dissonance in the former and reactance in the latter occurred for only those students who volunteered for treatment. The dissonance (high-responsibility-and-choice) group valued the treat-

Requests for reprints should be sent to Robert M. Gordon, 1251 South Cedar Crest Boulevard, Allentown, Pennsylvania 18103.

ment highly and claimed that it was very successful, whereas the reactance group devalued the treatment and was the only group of four who found the treatment to be unsuccessful. The nonvolunteers, who were not particularly interested in the treatment to begin with, were unaffected by the subsequent experimental manipulation.

Harris and Harvey claim that the subjects did not choose between evenly matched alternatives. They must have misunderstood my comment: "Surprisingly, many of the subjects had a definite preference" (Gordon, 1976, p. 800), taking it to mean that there was a *consistently* clear preference for one alternative over the other. This was not the case. I was surprised because there are no such forms of relaxation as "neuroglandular" and "cardiovascular." Yet people had definite preferences. Harris and Harvey contend that the processes of dissonance and reactance were not directly measured. This is true, but as far as I know, no theoretical construct is ever directly measured—it is only inferred.

Harris and Harvey claim that since there was no main effect of choice, they are correct in their argument. This circular reasoning assumes that the volunteering effects are not real. Harris and Harvey's alternative hypothesis erroneously assumes (a) that the volunteers expressed an earlier interest than the nonvolunteers; however, the volunteers and nonvolunteers expressed their differential attitudes at the same time. Harris and Harvey may be confusing the later manipulation to get the nonvolunteers into treatment with their initial attitudes. Also, the subjects' initial attitudes remained unchanged even after the treatment. They never became "volunteers." (b) The volunteers were less relaxed. Again, there were no significant volunteer pretreatment or posttreatment main effects in anxiety. (c) The volunteers expected preferential treatment. This, I suppose, is based on the above two assumptions. Treatment was not based on need or on a first-come, first-served basis.

Conclusions

Theoretically I would agree with Harris and Harvey's criticisms if their interpretations were

indeed true. The problem is certainly not in the improper understanding of social psychological theories. In attempting to reconcile perceived mutually exclusive findings, they have reinterpreted my study (Gordon, 1976) to seem imprecise. This is not an unusual form of dissonance reduction for researchers; Witness the plethora of straw-man controversies.

The only theoretical difference we may have is whether volunteering represents a methodological problem or an independent variable in its own right (Rosenthal & Rosnow, 1975). The volunteer issue has been a controversial one for some time. Perhaps part of the reason it has been so unwelcome is that it is so humbling. It infers that our procedures are only effective if people are willing to let them be effective. It infers that their initial motivations, feelings of personal responsibility, and resistances are more powerful than the treatment per se. The clinician, who has long observed this in therapy, cannot explain this away as self-selection or randomize or factor it away. The clinician must deal with these dynamics if the treatment is going to work. Volunteering is not a mistake—it is choice and responsibility.

Selecting a Short Form of the MMPI: Addendum to Faschingbauer

Norman G. Poythress, Jr.

Center for Forensic Psychiatry, Ann Arbor, Michigan

Faschingbauer offered guidelines to clinicians in the selection of Minnesota Multiphasic Personality Inventory (MMPI) short forms as substitutes for the full MMPI. This comment offers an addendum to Faschingbauer in the form of a review of empirical studies of the clinical validity of MMPI short forms and a discussion of the MMPI-168, which was not considered in Faschingbauer's earlier article. For diagnostic and interpretive accuracy, the empirical evidence to date seems to favor two short forms—the Faschingbauer Abbreviated MMPI and the MMPI-168—over the other available short forms.

In a recent review Faschingbauer (1976) discussed numerous clinical considerations one should make in selecting a short-form Minnesota Multiphasic Personality Inventory (MMPI) for clinical use in place of the full MMPI. In his article, Faschingbauer offered a critical analysis of four recently developed short forms—the Mini-Mult (Kincannon, 1968), the Hugo (Hugo, 1971), the Midi-Mult (Dean, 1972), and the Faschingbauer Abbreviated MMPI (FAM; Faschingbauer, 1974)—and addressed a variety of issues including (a) correlations of short-form scales with the full MMPI, (b) differences in item content, and (c) concordance rates between short forms and the full MMPI for Welsh code types.

Faschingbauer's review offered excellent guidelines for the clinician who may consider using an MMPI short form. If shortcomings are to be noted in his review, they would have to be that (a) he failed to include the MMPI-168 (Overall & Gomez-Mont, 1974) in his discussion, and (b) he excluded from discussion studies on the clinical (as opposed to statistical) validity of the various short forms. This comment offers an addendum to Faschingbauer (1976) and includes a discussion of the MMPI-168 and a review of the clinical validity studies of the MMPI short forms.

MMPI-168

The development and description of the Mini-Mult, the Hugo, the Midi-Mult, and the FAM

Requests for reprints should be sent to Norman G. Poythress, Jr., Center for Forensic Psychiatry, P.O. Box 2060, Ann Arbor, Michigan 48106.

was covered in Faschingbauer (1976) and will not be repeated here. The MMPI-168, developed by Overall and Gomez-Mont (1974), is the newest of the MMPI short forms. It consists of the first 168 items of the regular MMPI (the first 7 pages of the MMPI, Form R), which are scored by the regular scoring keys. These reduced MMPI raw scale scores are then converted to estimates of the full MMPI scale scores via either regression equations (Overall & Gomez-Mont, 1974, Table 1) or a conversion table (Overall, Higgins, & Schweinitz, 1976, Table 5). Early reports of the statistical concordance between the MMPI-168 and the full MMPI have been encouraging. Overall and Gomez-Mont reported correlations with the full MMPI scales ranging from .79 to .96, with a median correlation of .89 in a sample of 339 psychiatric patients. Newmark, Newmark, and Cook (1975) found that for male psychiatric patients, scale correlations between the MMPI-168 and the full MMPI ranged from .78 to .96, with a median of .88; for female psychiatric patients the range was from .77 to .93, with a median of .90. Further, in about 72% of cases the MMPI-168 predicted either the first or first and second peak scales found on the full MMPI. These initial findings for the MMPI-168 compare quite favorably with the correlations and concordance rates established for the other available short forms (Faschingbauer, 1976, Tables 1 and 2).

Statistical Concordance and Clinical Validity

For the practicing clinician who is looking for an MMPI short form appropriate for use in individual assessment, the relevance of statistical concordance data between various short forms

and the full MMPI must be questioned. Clearly, short-form to long-form scale correlations offer little of value concerning the utility of short-form profiles for individual profile interpretation and clinical decision making. The concordance for elevated peaks and code types is somewhat more relevant, and several investigators of the utility of MMPI short forms have offered negative evaluations of short forms based on concordance rates, which they judged to be unacceptably low. Hoffman and Butcher (1975), for example, found low hit rates for the Mini-Mult, the FAM, and the MMPI-168, and concluded that

there is insufficient evidence to advocate clinical use of the MMPI short forms. It seems that with such low classification accuracy in the short forms they would not simply plug into the existing interpretations and uses of the standard form without some modification and cautions. (p. 38)

Similarly, Griffin, Finch, and Edwards (1976) concluded their study of the Midi-Mult with the following warning: "The Midi-Mult cannot be used as an MMPI short form . . . because its scales are not sufficiently accurate in predicting the MMPI" (p. 56).

Other investigators have found these judgments and warnings to be premature or inappropriate. Poythress and Blaney (in press) noted:

This conclusion . . . suffers from three shortcomings. First of all, discordance of code type does not necessarily mean discordance of interpretation. One popular MMPI handbook (Gilberstadt & Duker, 1965) lists anxiety neurosis as an appropriate diagnosis for code types 1-3-9, 2-7, or 4, no two of which share even a single peak. Secondly, most investigators of code type concordance have concluded that the values they obtained were unacceptably low. However, if the code type concordance rate for test-retest studies of the full MMPI is utilized as the criterion, values such as those obtained by Hoffman and Butcher appear to be much more acceptable. For example, Faschingbauer (1974) found that for 61 subjects who took the full MMPI twice with only a one day interval, the same two-point code type was obtained in only 41% of cases. This suggests that the degree of slippage between long and short forms may not be markedly greater than the slippage between two long forms administered in close succession. Finally, the conclusion of Hoffman and Butcher and others is based on only an intermediate step in clinical interpretation. The final step, the clinician's profile interpretation, can be observed and measured directly; thus these investigators have made inferences where empirical investigation was called for. (p. 3)

The remainder of this comment is devoted to a brief review of empirical studies in which some

clinical judgment, decision, or interpretation was used to evaluate the utility of one or more of the MMPI short forms relative to the MMPI. It is asserted that this is perhaps the most relevant body of research literature for the practitioner to consider when contemplating the use of an MMPI short form.

Clinical Validity Studies: Diagnostics

Table 1 summarizes the findings of seven recent studies comparing one or more of the MMPI short forms to the full MMPI in diagnostic decision-making situations. In four of the studies shown, the consensual diagnoses of two or three PhD psychologists in their blind analysis of short- or long-form profiles are compared. These studies suggest that the FAM and MMPI-168 are about equal (near 80% agreement with the full MMPI) and are superior to two other short forms, the Midi-Mult and the Hugo. In three validity studies using various external diagnostic criteria, the MMPI-168 has been found slightly superior to the full MMPI in diagnostic validity. These studies suggest that for diagnostic purposes, the clinician should consider using the FAM or the MMPI-168 over the other available short forms, with a slight edge going to the MMPI-168.

Clinical Validity Studies: Profile Interpretation

To date there are but three studies that directly address the issue of accuracy of individual profile interpretation—Newmark, Conger, and Faschingbauer (1976); Newmark, Falk, and Finch (1976); and Poythress and Blaney (in press).

In the studies by Newmark and his associates, Newmark served as a blind interpreter of long-form and short-form profiles, generating 200- to 300-word interpretive statements about the patients whose profiles were provided. Subsequently, psychiatric residents in charge of patient care have rated his blind interpretive statements on a scale from 1 (totally inaccurate) to 5 (totally accurate), using their own knowledge of the patient as the criteria.

Newmark, Conger, and Faschingbauer (1976) found that the FAM compared favorably with the full MMPI, with 84% of the FAM interpretations and 92% of the full MMPI interpretations receiving a rating of either 4 (80% accurate) or 5 (totally accurate). In paired comparisons of long-form interpretations and short-form interpretations on the same patient, the full

Table 1
Diagnostic Validity of MMPI Short Forms

Study	Diagnostic outcome variable	Agreement between
Newmark, Cook, Clark, & Faschingbauer (1973)	Consensual diagnosis of 2 or 3 PhD psychologists—general categories of psychotic, neurotic, or personality disorder	MMPI and FAM: 76%
Newmark, Newmark, & Faschingbauer (1974)	same as above	MMPI and Midi-Mult: 43% MMPI and Hugo: 57% MMPI and FAM: 78%
Newmark, Owen, & Newmark (1975)	same as above	MMPI and Midi-Mult: 52% MMPI and Hugo: 64% MMPI and FAM: 78%
Newmark, Newmark, & Cook (1975)	same as above	MMPI and MMPI-168: 83%
Newmark & Finch (1976)	Same diagnostic decision as above for profiles, but hospital staff diagnosis utilized as criterion	MMPI & criterion: 84% MMPI-168 & criterion: 88%
Overall, Butcher, & Hunter (1975)	Using linear discriminant function to discriminate normals from psychiatric patients based on MMPI or MMPI-168 scores	MMPI-168 slightly superior to full MMPI discriminating normals from psychiatric patients
Overall, Higgins, & Schweinitz (1976)	Using multiple discriminant function for differential diagnosis across 10 major psychiatric diagnostic categories based on MMPI or MMPI-168 scores	MMPI-168 slightly superior to full MMPI in this differential diagnostic task

Note. MMPI = Minnesota Multiphasic Personality Inventory; FAM = Faschingbauer Abbreviated MMPI.

MMPI interpretations were more often rated above the FAM interpretations than was the reverse, but further analyses estimating validity coefficients (corrected for chance) for these two instruments yielded a coefficient of .94 for the full MMPI and .89 for the FAM. A second study, by Newmark, Falk, and Finch (1976), extended this same methodology to the FAM, the Hugo, and the MMPI-168. These investigators found that about 90% of the full MMPI interpretations received ratings of 4 or 5; the FAM, the Hugo, and the MMPI-168 received 82%, 45%, and 86%, respectively. The mean rating for the full MMPI interpretations was significantly higher than that for either the FAM or the Hugo but not for that of the MMPI-168. In paired comparisons, the MMPI interpretations were more often rated above the short-form interpretations, but this dominance was pronounced only for the Hugo. The MMPI-168 fared slightly better than the FAM and was judged to be, within the limits of the methodology of that study, interpretively equal to the full MMPI.

Poythress and Blaney (in press) noted the problems in the Newmark, Conger, and Fasch-

ingbauer (1976) and Newmark, Falk, and Finch (1976) methodology—the use of only one clinical interpreter and the gross measure of interpretive accuracy—and approached the assessment of short-form interpretive validity in a different manner. First, a large pool of clinical psychologists ($N = 29$) from various clinical and academic settings were recruited as blind interpreters of MMPI profiles. Second, profile interpretation was standardized and quantified by the use of a 30-item Q sort. For a given patient, four different raters were asked to rate profiles via the completion of a Q sort; two raters were mailed a profile based on full MMPI scoring, one rater received a Mini-Mult profile, and one rater received a FAM profile. The distribution of long-form/long-form Q -sort correlations was compared with each of the long-form/short-form correlation distributions to see if independent interpretations of the same long-form MMPI profiles were in fact more similar (i.e., correlated more highly) than were independent interpretations of a long form and a short form. The investigators found that the FAM was interpretively similar enough to the full MMPI to recommend it for clinical use; in 50% of com-

parisons, the FAM/MMPI Q-sort correlation was equal to or greater than the MMPI/MMPI Q-sort correlation for the same patient. However, the Mini-Mult did not generate interpretations sufficiently similar to those generated by the full MMPI to warrant a recommendation for its clinical use.

Discussion

Faschingbauer (1976) provided an extensive review of the literature on the ability of various short forms of the MMPI to predict various parameters of the full MMPI—such as elevated peaks or code types—and a discussion of differences in content among the various short forms. This article extends the review of Faschingbauer by providing a brief review of the empirical studies on the MMPI short forms in which an actual clinical decision or judgment was used as a dependent variable. It further includes a discussion of the recent MMPI-168, a short form that Faschingbauer's earlier article did not consider.

The needs and working constraints of the individual clinician will determine the selection of the MMPI short form. Unusual time constraints or illiterate subjects may dictate the use of one of the more abbreviated of the MMPI short forms, such as the Midi-Mult (86 items) or the Mini-Mult (71 items), which can easily be administered orally. The present review of validity studies, however, suggests that the FAM or the MMPI-168 should be selected over the other available short forms, since these two seem to provide the most accurate diagnostic and interpretive information. A slight edge in favor of the MMPI-168 is suggested, and it is the easiest of the short forms to administer. Form R of the regular MMPI can be used, with the patient being instructed to complete only the first 7 pages. Administration time is about 40 minutes, and conversion to full scale score estimates is easily accomplished via a conversion table.

A Note on the MMPI as a Suicide Predictor

James R. Clopton
Texas Tech University

Comments are offered on a recent article by Leonard on the Minnesota Multiphasic Personality Inventory (MMPI) as a suicide predictor. Her appraisal of former studies and her consideration of the differences between individuals with different suicidal behaviors are critically evaluated. Future research should emphasize the development of useful MMPI indices of suicidal risk and should recognize the need to cross-validate these indices.

A recent article by Leonard (1977) regarding the Minnesota Multiphasic Personality Inventory (MMPI) as a suicide predictor deserves comment. MMPI data obtained from psychiatric inpatients who had committed suicide were compared with two matched control groups, one of highly suicidal patients and the other of non-suicidal patients. Discriminant analyses revealed that the committed-suicide MMPI profiles were distinguishable from nonsuicidal profiles. Leonard discussed the personality differences between suicidal and nonsuicidal patients and emphasized the lack of homogeneity among suicidal patients.

Despite mentioning some of the limitations of previous research on suicide, Leonard (1977) declared that this research provides "encouraging results." However, to date there has been no indication that standard MMPI scales, MMPI profile analysis, or specially developed MMPI suicide scales can *reliably* predict suicide at *useful* levels. Two review articles (Clopton, 1974; Lester, 1970) show that the results of previous research are inconsistent and reveal that previous studies often have had major methodological flaws, such as combining individuals with different types of suicidal behavior into the same group (e.g., Broida, 1954). Leonard also appears to have overlooked research studies that have provided negative results. For example, Ravensborg and Foss (1969), using a multivariate analysis, found no differences in the MMPI profiles of patients who had committed suicide in a state hospital, patients who died of natural causes in the same hospital, and nonsuicidal patients.

Leonard's (1977) study and two earlier studies (Clopton & Jones, 1975; Devries & Farberow, 1967) have found some evidence that multivariate analyses can differentiate suicidal from nonsuicidal patients. Correct classification was obtained for 41% of the patients in the Devries and Farberow (1967) study and for 66% of the patients in the Clopton and Jones (1975) study. Leonard reported that for the female patients in her study, a discriminant function using seven MMPI scales correctly classified all 16 women who committed suicide and 14 of 16 female patients in a comparison group. Close examination reveals that these results may be less impressive than they appear. As Leonard explained, the clinician wants a single index or other straightforward means of determining suicidal risk from MMPI data, and the variables in a discriminant analysis form a complex cluster. None of the three studies using multivariate procedures have examined the usefulness of these procedures to clinicians faced with the task of predicting suicidal behavior. Another consideration not mentioned by Leonard is that before multivariate procedures can be considered reliable in classifying patients as suicidal or nonsuicidal, they need to be cross-validated. That is, the combination of differentiating variables needs to be derived in one comparison of suicidal and nonsuicidal individuals and then extended to new samples. The percentage of correct classifications could be considerably lower in the validation samples. None of the three studies using multivariate procedures have cross-validated their procedures.

Leonard (1977) stressed the diversity existing among different suicidal groups, and at one point she stated that increasing the sample size in suicide studies by including suicide threateners or attempters with those who commit suicide is appealing but not justified. She stated that the populations (actual suicides, suicide attempters,

The author thanks Roger Greene and Donald H. Baucom for their helpful suggestions.

Requests for reprints should be sent to James R. Clopton, Department of Psychology, Texas Tech University, Lubbock, Texas 79409.

and suicide threateners) are obviously different. One is puzzled then to find that the high-suicide comparison group in her study contained patients with histories of suicide attempts and/or prolonged threats and preoccupation. Combining patients who threaten suicide with those who make suicide attempts is a questionable procedure. Previous MMPI research reveals that patients threatening suicide have the most deviant MMPI profiles of any suicidal group and that there are differences in the MMPI profiles of patients who threaten suicide and those who attempt suicide (Farberow, 1956; Farberow & Devries, 1967; Rosen, Hales, & Simon, 1954; Simon & Gilberstadt, 1958).

Leonard (1977) has perpetuated the notion that the study of suicide attempters is not a valid way to gain information about individuals who commit suicide. She stated that the two populations are different, and in support she noted that approximately three times more females than males attempt suicide, but approximately three times more males commit suicide. Despite these sex differences, the prevailing view is that suicide attempters and those who commit suicide can be regarded as members of the same population (Stengel, 1972). Chance often plays a critical role in influencing the outcome of a suicide attempt, regardless of the lethality of the attempt. Also, those who commit suicide frequently have prior records of unsuccessful attempts. In Leonard's committed suicide group, 80% of the males and 75% of the females had a history of one or more suicide attempts prior to committing suicide. Finally, observed sex and age differences between those who commit suicide and those who attempt suicide may be largely due to incidental cultural factors. The higher rate of committed suicide among males is probably related to their use of more violent methods, such as gunshot, which provide less opportunity for rescue than self-poisoning, the preferred method of females. Because men have more access to instruments of violence and more training in their use, it is reasonable to expect more of their suicide attempts to be successful.

Leonard's (1977) study is a valuable contribution to the research literature, but neither her results nor the findings of previous studies have indicated that the MMPI can reliably predict suicide at useful levels. Multivariate procedures, such as those used by Leonard, have not been cross-validated, nor have they been demonstrated to be of practical value to clinicians attempting to predict suicidal behavior.

Leonard (1977) combined patients who threatened suicide and patients who attempted suicide

into one group. However, patients who threaten suicide are the most distinct suicide group. It is possible that the patients who attempted suicide were more similar to the patients who committed suicide than to the patients who threatened suicide. Despite Leonard's comments to the contrary, the current view is that patients who attempt suicide are probably all members of the same population regardless of the success of their attempts.

Response to "A Note on the MMPI as a Suicide Predictor"

Calista V. Leonard
University of California, Los Angeles

Response is made to comments by Clopton on an article by Leonard on the Minnesota Multiphasic Personality Inventory (MMPI) as a suicide predictor. Clopton's viewpoint that patients who attempt suicide are probably all members of the same population regardless of the success of their attempts is discussed. His concern that future research should emphasize the development of useful MMPI indices of suicidal risk and should recognize the need to cross-validate these indices is endorsed.

Clopton's (1978) main concern in his comments on Leonard (1977) seems to center about his belief that "patients who attempt suicide are probably all members of the same population regardless of the success of their attempts" (p. 336). This is an individual viewpoint rather than a "current view." It does not take a statistician to deduce that if attempted suicides are all from the same population, then one would expect male suicides, for example, to be equaled by female suicides instead of being approximately three times more numerous. Unquestionably, there is overlapping between the groups, but many suicides have never attempted or overtly threatened suicide (Robins, Gassner, Kayes, Wilkinson, & Murphy, 1959), and many attempted suicides who have seemed lethally suicidal do not go on to commit suicide (Pitts & Winokur, 1964).

Another concern expressed by Clopton is that negative results were not reported, and I agree in this respect. However, negative results must be studied for comparability, and the Ravensborg and Foss (1969) study that he cites (Clopton, 1978) contained control groups that were not matched with the committed suicide group on important variables. The control groups were significantly older, less educated, and had lower intelligence scores ($p < .001$). One must wonder why the multivariate analysis found no significant differences in Minnesota Multiphasic Personality Inventory (MMPI) profiles in spite of these important group differences.

A further criticism with which I agree wholeheartedly is that cross-validation and helpful

hints for clinicians are sorely needed in studying the MMPI as a predictor for suicide. Even though Clopton (1978) did not report a cross-validation for his study (Clopton & Jones, 1975), his discriminant analysis of the data lent some support to the use of MMPI profiles to identify suicidal psychiatric patients. His caution in this excellent study concerning the need for identifying the obtained differences in profiles is well taken.

I would like to conclude this response with a note on armchair theorizing, which I enjoy and define as "making hypotheses without providing evidence for them" and which seems to me to be the forerunner of attempts at finding testable answers. Clopton (1978) theorizes that men commit suicide more frequently because they have more access to instruments of violence and more training in their use, whereas women are less frequently suicides because they use self-poisoning and are more readily rescued. The immediate response, of course, is "but any ambulatory and determined would-be suicide could select jumping as a method, and most women drive and could use a car lethally even if they didn't have training or access to guns." Which brings the issue directly back to the cultural and personality variables that lead one person to choose a gun, another to make a half-hearted pill-taking attempt, and another to choose a nonsuicidal solution to environmental stresses. This is what research on the prediction of suicide is all about. What environmental and personality differences make one person more self-lethal than another?

Brief Reports

Characteristics of the Emotional Responsiveness of Sensitizers and Repressors to Social Stimuli

Glenn A. Miller
Arizona State University

William Nuessle
University of Kentucky

TAT-like (Thematic Apperception Test) stimuli of positive, negative, and neutral affect were presented to 30 sensitizers, 30 intermediates, and 30 repressors to test Lefcourt's formulation that sensitizers positively value emotional expression and repressors devalue such expression. Contrary to the expectation based on an extension of Lefcourt's model, sensitizers did not significantly differ from repressors on the number of positive, negative, or total affect words in their stories. His model appears consistent only with the responses of subjects to negative affective stimuli and not with their responses to positive affective stimuli.

The traditional interpretation of repression and sensitization as referring to defensive dispositions to anxiety cues was challenged by Lefcourt (1966). He suggested that sensitizers and repressors differ in their valuation of emotional expression, with sensitizers positively and repressors negatively valuing such expression. For example, both repressors and sensitizers describe themselves in positive ways. The self-descriptions of sensitizers, which have been typically interpreted as negative, are actually positive from their viewpoint because they perceive their "admissions [of emotionality] as revealing honesty with one's self, and a lack of fear of self-disclosure" (Lefcourt, 1966, p. 445).

This reformulation minimizes the importance of anxiety cues and increases the relevance of the emotional expressiveness of repressors and sensitizers to positive and neutral stimuli. The present study attempted to determine whether Lefcourt's theory would predict the emotional expressiveness of repressors and sensitizers to positive and neutral as well as to negative stimuli.

The subjects, 90 male introductory psychology students, were divided on the basis of Byrne's Repression-Sensitization scale (Byrne, 1961) into three equal groups of sensitizers, intermediates, and repressors and were presented with eight TAT-like (Thematic Apperception

Test) slides to which they wrote stories. One third of each group received stimuli of positive, neutral, or negative affective tone. The dependent measures were the number of positive, of negative, and of total affective words contained in the stories.

The clearest test for the extension of Lefcourt's interpretation to both positive and negative emotional stimuli is the comparison of the three subject groups on the total number of emotional words to all three types of stimuli combined, with differences in length of story covaried out. Contrary to Lefcourt's theory, the sensitizers did not exceed repressors and intermediates on negative, positive, or total affective words. An interaction between the affective tone of the stimuli and the three subject groups occurred in the analysis of both the total emotional words and total negative words, $F(4, 71) = 2.82, p < .05$; $F(4, 71) = 2.50, p < .05$. The interaction for total emotional words is a consequence of the fact that sensitizers exceeded repressors on the negative slides but repressors gave more emotional words to the positive and neutral slides.

In the analysis of total positive words, there were no significant differences between groups and there was no interaction between subject groups and types of stimulus slides. In fact, sensitizers gave fewer positive words than repressors. This difference in means is opposite in direction, although not significantly, to that which would be predicted from Lefcourt's interpretation.

Requests for reprints should be sent to Glenn A. Miller, Department of Psychology, Arizona State University, Tempe, Arizona 85281.

Thus the greater emotional expressiveness of sensitizers, as compared with repressors, appears to be limited to responses to negative stimuli. This would seem to mean that Lefcourt's interpretation of the repression-sensitization dimension as a reflection of differential valuation of emotionality requires additional constructs to account for the interaction between the affective tone of the stimuli and the status of subjects as repressors and sensitizers.

Factors Influencing Lower-Class Black Patients Remaining in Treatment

Anthony Vail

San Diego County Mental Health, San Diego, California

Early termination from individual therapy in a community mental health clinic was studied with lower-class black patients assigned to therapists who were black or white. The only significant correlate was the interaction between sex of therapist and sex of patient. Patients remained longer with therapists of the opposite sex. No significant correlations were found between remaining in treatment and black patients' attitudes toward whites, patients' perceptions of therapists' understanding and acceptingness, or patient-therapist discrepancies in their perception of therapy.

This study explored early termination from psychotherapy in an inner-city community mental health clinic in Philadelphia. The 32 black male and 55 black female lower-class patients for this study were obtained after they had had clinical evaluations. They were randomly assigned to 1 of 10 staff therapists who were black or white, male or female. After the first therapy session, the therapists filled out the discrepancy scale described below. The patients were orally presented with this and other scales by an experimental interviewer.

Attitudes toward whites were assessed by an attitude behavior scale of blacks toward whites. Two levels of this scale were used that examined the patients' personal behavior and their attitudes toward societal stereotypes.

Patient-therapist discrepancies in perception of therapy were measured by a scale constructed for this study. It included an inquiry as to what the patients considered their most important problem; questions as to whether the therapy matched the patients' expectations; a sampling of the patients' attitudes toward seeking professional, psychological help; estimates of the therapists' understanding and acceptingness as perceived by the patients; and questions about the patients' preference for certain types and degrees of therapist activity.

Finally, patients' perceptions of their therapists' understanding and acceptingness were measured in detail.

The 43 patients who came for three sessions or less were considered the dropouts; the 44 who came for four or more sessions were considered

remainers. To analyze for effects of patient-therapist similarity in race and sex on continuation in treatment, a three-dimensional contingency table was used.

The only result significant at the .05 level was the Sex of the Therapist \times the Sex of the Patient interaction. The race of the therapist did not matter statistically. Most of the interaction originated with male therapists being less effective with black male patients than with black female patients. Female therapists were also less effective with patients of their own sex, although this was only about half as pronounced as the finding for male therapists. The interaction effect was opposite to the direction predicted. At least 29% of the variance among patients' remaining in treatment was accounted for by this interaction effect.

No significant correlations were found between remaining in treatment and the black patients' attitudes toward whites on either of two levels; patients' perception of their therapists' understanding and acceptingness; or the similarity of their view of therapy to that of their therapists.¹ In all of these analyses, it did not matter statistically whether the therapists were black or white.

It seems worth looking further into the dynamics of the cross-sex phenomenon between therapists and lower-class patients to see if it is based on the attractiveness of a heterosexual encounter, inhibitions associated with being painfully revealing of oneself before a therapist of the same sex, or some other reason.

Received February 12, 1976 ■

Requests for reprints and for an extended report of this study, and for a copy of the scales used, should be sent to Anthony Vail, 12732 Gibraltar Drive, San Diego, California 92128.

¹ A discussion of some small but significant correlations between Patient-Therapist Discrepancy subscales and dropout can be found in the extended report.

Effects of Explanation and Information Feedback on the Illusory Correlation Phenomenon

Ronald W. Waller and Stuart M. Keeley
Bowling Green State University

An attempt was made to attenuate the illusory correlation phenomenon existent in one set of diagnostic stimulus materials, Draw A Person, through training on another set, Rorschach. Three training methods were tried: information feedback plus explanation, information feedback only, and explanation. None of the training conditions attenuated the illusory correlation effect when no relationship existed in the stimulus set. Significant attenuation occurred only when a negative correlation existed.

Even though it seems clear that clinical psychologists have considerable room for improvement in making judgments, only recently have researchers begun to isolate factors contributing to nonoptimality of judgment and to the frequently misplaced faith in such judgments. One such factor is the presence of "illusory correlations"; that is, subjects with strong *a priori* expectations often respond to expected relationships rather than to the relations actually in the stimulus materials (e.g., Chapman & Chapman, 1969). This tendency to maintain a belief in illusory correlates when the evidence does not support such a belief presents a major obstacle to making valid clinical judgments. This study asks the question, "Can this obstacle be overcome by sensitizing judges to the phenomenon?" Such training of judges would have maximum utility if it were to generalize to a variety of judgment tasks. The present study examines whether special training on illusory correlation using Rorschach test stimulus materials will reduce the illusory correlation effect for a second set of materials, the Draw-A-Person (DAP) task.

Subjects were 120 volunteer undergraduate introductory psychology students. Thirty subjects were randomly assigned to each of four different training conditions: (a) explanation, (b) information feedback, (c) explanation and information feedback, and (d) control. Subjects assigned to each of the four training conditions were divided into three subgroups ($n = 10$), each receiving a different set of generalization stimulus materials. Thus, there were 12 groups in all. Each group participated in three phases: (a)

pretraining judgments, (b) training, and (c) posttraining generalization judgments.

In the pretraining phase, subjects made judgments about how they believed specified Rorschach and DAP cues were related to various symptoms. In the training phase, subjects in each training group were exposed to the same three sets of 24 Rorschach stimuli each. Each set included one cue-symptom pair that had been found to be an illusory correlate in previous research or else had been rated as being related by more than 50% of a group of 25 introductory psychology pilot subjects. Set 1 contained no relationship among cues and symptoms. Set 2 contained a strong negative relationship between the illusory correlate pair; and Set 3 contained a strong positive relationship.

Subjects in the information feedback and explanation training condition (FE) were given an explanation of the nature of the illusory correlation phenomena and were informed of research findings related to this phenomenon prior to viewing the three training sets. They were warned that illusory relationships might bias their own judgments of the stimulus materials and were cautioned to try to avoid this kind of bias. After viewing each stimulus set and judging the cue-symptom relationships, subjects were given the actual cue-symptom relationships contained in that set to compare with their predictions. Subjects in the explanation (E) condition received a training procedure identical to the FE group, except they received no information concerning the actual relationships contained in the stimulus materials. Subjects in the information feedback (F) condition were only given feedback information about the true cue-symptom relationships. Control subjects (C) received no information concerning the actual

Requests for reprints should be sent to Stuart M. Keeley, Department of Psychology, Bowling Green State University, Bowling Green, Ohio 43403.

cue-symptom relationships and no explanation of the illusory correlation effect.

In the generalization judgment phase, each subgroup was exposed to one of three sets of DAP stimulus materials, each set varying in actual cue-symptom relationships. Stimuli were similar to those used by Chapman and Chapman (1967). Each set contained the illusory correlate of broad shoulders and muscular drawing characteristics and the symptom "he is worried about how manly he is." The three cue-symptom relationships were (a) no relationship among DAP drawing characteristics and the symptom statements (DS 1), (b) a strong negative relationship between the illusory correlate pair (DS 2), and (c) a strong positive relationship between the illusory correlate pair (DS 3).

Subjects made two kinds of responses during each phase. First, they used a 7-point scale indicating the likelihood that the patient had each symptom given a specified cue. Second, they rated the confidence they had in the judgments they made about the relationships in each stimulus set by marking a 15-cm line.

As expected, a strong a priori bias existed in the pretraining estimates of the relationship between the illusory cue-symptom pairs. The majority of subjects in all groups reported positive relationships for both Rorschach and DAP illusory pairs.

Likelihood ratings of the illusory DAP cue-symptom combination were analyzed by a three-way fixed effects analysis of variance (4 Training Conditions \times 3 Stimulus Sets \times 2 Judgment Times), with the subject factor nested under both training conditions and stimulus sets. Main effects were found for both stimulus set ($p < .01$) and time of judgment ($p < .01$); and a significant interaction was found between stimulus set and time ($p < .01$). The source of the interaction is clear. Subjects behaved in a virtually identical fashion on pretraining and posttraining judgments to DS 1 and DS 3 sets, reporting a positive relationship. However, subjects in all training conditions responded very differently to the DS 2 stimulus set following training than prior to training. Their judgments shifted from positive to either zero or negative. This differential shift is supported by the findings of a simple main effect of stimulus set for the second set of judgments ($p < .01$) and none for the first set.

A three-way analysis of variance on confidence judgments showed only one significant effect—time of judgment ($p < .01$). Subjects became more confident in their judgments from pretraining to posttraining, regardless of which training condition they were in and regardless of which stimulus set they were exposed to.

Sensitizing subjects to the illusory correlation phenomenon or Rorschach materials through feedback about actual relationships, explanation of the phenomenon, or both did not attenuate the tendency to see positive cue-symptom relationships when no relationship actually existed. However, negative relationships between illusory correlates markedly attenuated the effect. Such findings suggest that subjects do attend to the evidence. They also suggest that the number of confirmations of the original biased expectancy relative to the number of disconfirmations may be a crucial determinant of whether the original belief is maintained.

It is important to note that in the typical illusory correlation demonstration, subjects are provided with only affirmations of the symptoms; negations must be implied. Thus, they typically see some instances of cue present, symptom present for the illusory pair but never see the cue with an explicit statement of the absence of the symptom. Only a few affirmatives may be necessary to maintain the illusory belief.

The present study provides further suggestive evidence that human judges have a difficult time using evidence appropriately in the face of uncertainty. Short-term explanation and/or feedback procedures do not seem to be a sufficient remedy for this particular kind of error in human judgment. Whether long-term training procedures would attenuate the effect is presently an empirical question.

The 4-3 MMPI Profile Type: A Failure to Replicate

Jeffrey A. Buck and John R. Graham
Kent State University

Using a sample of 65 prison inmates, the incidence of violent crimes for persons with the 4-3 Minnesota Multiphasic Personality Inventory profile type and with other two-point code types was compared. The results failed to replicate the findings of some earlier investigators, who reported that violent behaviors are more common for persons with the 4-3 profile type. The failure to identify a significant relationship between the 4-3 profile type and violent behavior suggests that caution should be exercised in generalizing to populations that differ from those in which the relationship between violence and the 4-3 profile type is established.

Previous investigations of the Minnesota Multiphasic Personality Inventory 4-3 profile type have yielded inconsistent results. Some studies (e.g., Davis & Sines, 1971; Persons & Marks, 1971) have indicated that subjects producing the 4-3 profile are prone to act in more aggressive and violent ways than subjects not producing the 4-3 profile. Other studies (e.g., Gynther, Altman, & Warbin, 1973) have not found violence or hostility to be characteristic of persons with the 4-3 profile. Two explanations offered for this disparity have been differences in the ages of the subjects studied and the ways in which the 4-3 profile type have been defined. The present study attempted to gain information about both of these possible sources of variance.

Subjects were male inmates of a medium-security penitentiary for adult male felons located at Marion, Ohio. The incidence of violent crime was examined in a sample of 65 prisoners producing a 4-3 profile type and 64 not of this type. Violent crime was defined as murder, rape, aggravated assault, or robbery. The 4-3 and non-4-3 groups were separated into "old" subjects (30 or older) and "young" subjects (under 30). Within each of the resultant subgroups, the number of subjects committing violent and nonviolent crimes was determined and a chi-square test was made to determine if the subgroups differed on this variable. In addition to this over-

all comparison, different combinations of the subgroups were examined for possible differences on the violence measure. Analyses of variance also were performed to determine if the absolute and relative elevations of Scales 3 and 4 influenced the relationship between the 4-3 profile type and violent or aggressive behavior. All of the above tests were performed separately for black and white subjects. None of the relevant comparisons was significant.

Comparisons of the methodology of the present study with those of previous ones indicate that the way in which the 4-3 profile has been defined and the criterion measures of aggressive and violent behavior cannot completely account for the differences in findings between this investigation and others. A possible explanation for these differences is that the subjects in this study came from a facility in which the most aggressive and violent prisoners already had been selected out and sent elsewhere. The failure to identify a relationship between the 4-3 profile type and aggressive and violent behavior in this study suggests that caution should be exercised in generalizing to populations that differ from those in which the relationship between violence and the 4-3 profile type is established.

Congruence of Parental Perception, Marital Satisfaction, and Child Adjustment

Lucy Rau Ferguson and Deborah R. Allen
Michigan State University

Fathers and mothers of 95 children 5-7 years old completed the Locke-Wallace Scale, the Interpersonal Checklist, and the Children's Behavior Checklist to assess marital satisfaction, congruence of self- and mate-perceptions, and agreement in parents' perceptions of their child and child adjustment, respectively. All variables were significantly, positively intercorrelated. Strongest association was between congruence in parents' perceptions of the child and child adjustment. Similarity in partners' self-concepts and psychological empathy were significantly associated with marital satisfaction and child adjustment. A general dimension of family harmony (vs. conflict) is seen as contributing to children's social adjustment.

Children who exhibit deviant social behavior generally come from families characterized by marital dissatisfaction and discrepant parental attitudes. In a recent study based on small samples (Ferguson, Partyka, & Lester, 1974), parents of well-adjusted children showed closer agreement in their perceptions of their child than parents of clinic-referred children. It was predicted that in the general population, parents who described their children as more favorably adjusted would show closer agreement in their perceptions of their child, would report greater marital satisfaction, and would show greater agreement between descriptions of themselves and descriptions of them by their spouses.

Letters requesting cooperation in a research study were distributed to all parents of kindergarten, first-, and second-grade children in the Holt, Michigan, Public School System (approximately 1,000 children). Two hundred four families returned postcards indicating their willingness to participate in the study. Parents of 95 children (51 males and 44 females between 5 and 7 years old) completed the following questionnaires: Marital adjustment and satisfaction were assessed for each parent by his/her responses to the Locke-Wallace Scale (Locke & Wallace, 1959). The Interpersonal Checklist (LaForge & Suczek, 1955) was used to assess parents' perceptions of self and spouse. The Children's Behavior Checklist (CBCL) was the in-

strument used to assess parents' perceptions of their child. It consists of 154 interpersonal and symptomatic items referring to the behavior of children; the parent checks whether each item is applicable to the child and/or characteristic of him/her. The CBCL was also used as a measure of child adjustment. Sixty-six items have been found to discriminate significantly between clinic-referred and nonclinic (adjusted) children, with 32 being more characteristic of clinic-referred children and 34 being more characteristic of nonclinic children (Ferguson et al., 1974). Adjustment is calculated by subtracting each parent's score on the 32 clinic items from his/her score on the 34 nonclinic items; the mean of the mother's and father's scores yields a combined adjustment score for the child.

Interitem phi coefficients expressed the agreement between the husband's perception of himself and his wife's perceptions of him and between the wife's perceptions of herself and her husband's perceptions of her. Agreement in parents' perceptions of their child was determined by calculating the correlations between the mother's ratings of her child on the CBCL and those of the father.

Distributions of Locke-Wallace scores and of CBCL child adjustment scores were all negatively skewed; thus this is a sample of families who preponderantly reported themselves as happy and well-adjusted. Associations between the various measures of congruence of parental perception (of spouse and child), marital satisfaction, and child adjustment were examined by means of product-moment correlation coefficients. For the sexes combined all correlations were significant at the .05 level in the predicted direc-

Figure 1. Intercorrelations of variables based on combined sample.

tion; 9 out of 13 were significant at the .001 level.

Figure 1 shows the interrelations among the variables.

Parents' agreement in viewing their child was closely associated with congruence in their perceptions of each other, and each of these variables in turn was significantly related to marital satisfaction. Thus we seem to be tapping a more general dimension of family harmony that underlies the child's social adjustment. When parents see their child as possessing the characteristics of well-adjusted children, they also tend to agree closely in their perceptions of all aspects of their child's behavior, to express satisfaction with their marriage, and to see their spouses the way their spouses see themselves. Further research is

underway to confirm these relationships using an independent measure of child adjustment.

A Factor Analysis of Assertive Behaviors

Joseph S. Pachman, David W. Foy, and Frank Massey
Veterans Administration Center, Jackson, Mississippi

Richard M. Eisler
Virginia Polytechnic Institute and State University
Blacksburg, Virginia

Five objective measures of interpersonal behavior presumed to be tapping "assertiveness" were factor analyzed. In addition, each behavioral measure was correlated with a subjective global rating of assertiveness. Four of the behavioral measures loaded highly on a general factor of assertiveness. The fifth behavioral measure loaded highly on a separate factor, Response Latency. All behavioral measures with the exception of response latency evidenced significant correlations with the subjective rating of global assertiveness.

Systematic progress in the area of assertiveness training has been hampered by a general lack of consensus as to what specific responses are involved in behaving "assertively." Some workers have chosen to define assertive behaviors intuitively and then modify these components (Wolpe & Lazarus, 1966). More recently, Eisler, Miller, and Hersen (1973) have identified specific verbal and nonverbal behaviors that distinguished psychiatric patients judged to be relatively assertive from those who were unassertive.

The present study was designed to statistically investigate the relative contributions of these presumed behavioral components of assertiveness with a factor-analytic procedure (principal axis method, varimax rotation). A second purpose was to compare subjective global ratings of assertiveness with specific behavioral measures.

The subjects were 55 males hospitalized for treatment of alcoholism. We constructed a series of five vocally related interpersonal encounters requiring assertive responses. A male respondent was employed to prompt subjects' responses to these situations. Responses were videotaped and rated on the following components of assertion: duration of eye contact, duration of reply, latency of reply, statements indicating "compliance" with the respondent's unreasonable requests and assertive requests for the respondent to change his behavior, and a global measure of assertiveness.

The results indicated that duration of reply (.69), duration of eye contact (.70), noncompliant speech content (.74), speech content requesting new behavior (.78), and overall asser-

Table 1

Correlations Between Global Assertiveness and Behavioral Components of Assertiveness

Behavior component	r

tion (.75) were all loaded highly on Factor 1 (Assertiveness). However, latency of reply loaded nearly entirely (.93) on a separate factor (Factor 2, Response Latency). In addition, correlation coefficients obtained between the subjective global measure of assertiveness and the other behavioral measures, with the exception of latency of reply, were statistically significant.

The results corroborate the importance of the previously identified component behaviors (Eisler et al., 1973), with the exception of response latency, in reflecting assertiveness (see Table 1). The utility of a subjective global rating of assertiveness by trained observers was also demonstrated in view of the significant correlation coefficients obtained between this measure and the objective behavioral measures of assertion.

Life Change, the Sensation Seeking Motive, and Psychological Distress

Ronald E. Smith, James H. Johnson, and Irwin G. Sarason
University of Washington

The relationship between life change and psychological distress as a function of the sensation seeking motive was investigated. Scores on Lanyon's Discomfort scale were unrelated to positive and total life change scores but were significantly related to amount of negative life change occurring over the previous year. However, as predicted, this relationship was restricted to subjects low in sensation seeking; high sensation seekers are apparently more tolerant of negative life change.

The role of life change in physical and psychological well-being has received considerable empirical attention in recent years, and degree of life change has been shown to be significantly related to both physical illness and measures of psychopathology. Most of the life stress research has been based on the possibly erroneous assumption that change per se is stressful, regardless of whether it is perceived by the individual to be positive or negative. In addition, the role of personality variables as mediators of responses to life change has been virtually ignored.

The present study examined the relationships between both positive and negative life change and a measure of psychological distress as a function of subjects' scores on the Sensation-Seeking Scale (SSS; Zuckerman, Kolin, Price, & Zoob, 1964). It was hypothesized that low sensation seekers, who presumably have a low optimal level of stimulation, would be more negatively affected by stressful life changes than would high sensation seekers.

Forty-two male and 33 female college undergraduates were administered the 22-item SSS and the Life Experiences Survey (Sarason & Johnson, 1976). On the latter measure, subjects indicate which of a series of life changes they have experienced during the past 12 months, and they rate the positiveness or negativeness of each experienced change. Positive, negative, and total life change scores are obtained by summing these ratings. (The positive and negative change scores have been found in this and other studies to be essentially uncorrelated with one another.)

In the present study, subjects scoring above and below the median of the positive, negative, and total life change distributions and above and below the median of the SSS were assigned to cells of three separate 2×2 factorial designs. The subjects also completed the Discomfort scale of the Psychological Screening Inventory (Lanyon, 1970), which served as the dependent variable measure of psychological distress.

No significant main or interaction effects were found in analyses of variance involving either the positive or total life change scores. However, a significant main effect for negative life change was found, $F(1, 71) = 4.75$, $p < .05$, with high-change subjects ($M = 10.97$) having higher scores on the Discomfort scale than low scorers ($M = 8.71$). The interaction effect closely approached but did not attain significance. Subsequent Duncan multiple-range tests of cell means showed no significant Discomfort scale differences between high sensation seekers who differed in negative life change. However, among low sensation seekers, high-negative-change subjects ($M = 12.44$) had significantly higher distress scores than did those who had experienced low levels of negative change ($M = 9.00$). The role of sensation seeking as a moderator variable was also indicated in a correlational analysis that disclosed a significant relationship ($r = .35$) between negative life change scores and Discomfort scores in low sensation seekers but no significant relationship ($r = .15$) in high sensation seekers.

The results of this study suggest that life changes are related to psychological distress only if the individual perceives them to be negative, and that the sensation seeking motive influences

Relation of Patient Attributes to Perceptions of the Treatment Environment

Rudolf H. Moos
Social Ecology Laboratory
Stanford University

Evelyn Bromet
Department of Psychiatry
University of Pittsburgh

The social climate of four residential alcoholism programs was assessed using the Community-Oriented Programs Environment Scale (COPEs). COPEs perceptions were essentially independent of 18 patient background, psychosocial functioning, and alcohol-related characteristics. Considered in conjunction with previous research in other psychiatric and nonpsychiatric settings, the results indicate that perceptions of the social climate of treatment programs are not simply measures of the personal characteristics of the perceivers.

A number of instruments have recently been developed to measure the social-environmental characteristics of psychiatric treatment programs. Several of these techniques assess the treatment environment by asking patients and/or staff about the relevant characteristics of their milieu. In using these "perceived environment" scales, the usual procedure is to average responses from a set of patients and/or staff and to assume that these mean values describe the particular environment being studied.

One problem with this procedure is that there may be substantial differences among individuals in the way in which the "same" treatment environment is perceived. These individual differences have raised the important issue that scales measuring environmental perceptions may reflect background and/or personality characteristics of the perceivers rather than independent attributes of the environment.

The limited empirical evidence that is available indicates that personal characteristics are only minimally related to environmental perceptions (Moos, 1974). The purpose of the present study was to provide more extensive evidence on this issue by relating a wide range of background and intake functioning characteristics to patients' perceptions of the social climate of residential alcoholism programs.

The research population was composed of 326 alcoholic inpatients treated at one of four residential alcoholism programs. Two of the programs were in an urban area (Salvation Army

and a public hospital unit) and were populated by patients who tended to be single, separated, or divorced; residentially mobile; and average or below average in occupational status, income, and education. The other two programs were located in suburban areas and admitted patients who were more often from middle- to upper-middle class backgrounds, who were residentially stable, and who were living with their families. Therefore, we combined patients in the first two programs (Study Group 1; $n = 171$) and those in the latter two programs (Study Group 2; $n = 155$).

Shortly after admission to the programs, patients were administered a detailed background information form, which obtained information about sociodemographic characteristics (nine items), alcohol consumption, behavioral impairment, physical impairment, subjective rating of drinking problem, drinking pattern for the month before entering the program, previous hospitalization for alcoholism, occupational functioning, social functioning, and psychological well-being. There was substantial variability in these sociodemographic and premorbid functioning characteristics due to within-program differences among patients.

Approximately 2-3 weeks after admission, patients were administered the Community-Oriented Programs Environment Scale (COPEs) to evaluate the social climate of their program. The COPEs is composed of 10 subscales: Involvement, Support, Spontaneity, Autonomy, Practical Orientation, Personal Problem Orientation, Anger and Aggression, Order and Organization, Program Clarity, and Staff Control (Moos, 1974). The proportion of subscale variance accounted for by differences among the four programs averaged 20% and ranged from 29.5% for Order and Or-

Requests for reprints and for an extended report of this study should be sent to Rudolf H. Moos, Department of Psychiatry, Stanford University, Stanford, California 94305.

ganization to 9.2% for Program Clarity, indicating that there was substantial subscale variability within each of the programs.

Pearson correlation coefficients between the patient attributes and the 10 COPEs subscales were computed for the two study groups. A series of multiple regression analyses were then performed to assess the overall contributions of the 18 patient attributes to perceptions of the treatment environment. Ten multiple regression analyses (1 for each of the 10 COPEs subscales, which were the dependent variables) were run for each of the two study groups.

Only 7 of the 180 correlation coefficients were .20 or greater in Study Group 1, whereas only 1 of the 180 correlations was .20 or greater in Study Group 2.

Two of the 10 multiple regressions (for Support and Practical Orientation) were statistically significant ($p < .05$) in both study groups; however, none of the 180 possible relationships between the 18 patient background and functioning variables and the 10 COPEs subscales were replicated in the two groups. For example, in Group 1, patients who were better educated and more residentially stable perceived less emphasis on Practical Orientation, whereas patients who were functioning better socially perceived more emphasis on this dimension. These relationships were not replicated in Study Group 2, however, in which Catholic patients and patients who were drinking less and who showed less physical impairment perceived more emphasis on Practical Orientation.

Overall, there was a slight tendency for better educated patients to be somewhat more negative, and for patients with fewer symptoms and less reported drinking severity to be somewhat more positive, in their evaluations of the social climate of their program. However, the correlations were very low and represented less than 5% of the entire correlation matrix. The most parsimonious conclusion to be drawn from these data is that perceptions of treatment environments are only minimally related to patients' background and personality characteristics.

Even though environmental perceptions are independent of a broad array of background characteristics, they are related to an individual's role position in an environment. In general, those responsible for an environment view it more favorably than those not responsible. In addition, staff members of different roles may perceive the same programs differently; for example, nurses and day personnel tend to feel that the professional staff is more supportive than do

aides and evening or night personnel. These findings probably reflect differences in the subenvironments experienced by different individuals.

Environmental perceptions are also related to how well people actually function in an environment. People who see their environments more positively tend to be more satisfied with and perform better in those environments. For example, patients who perceive their programs more positively are more likely to participate in aftercare services (Pratt, Linn, Carmichael, & Webb, 1977), whereas residents who perceive their programs more negatively are more likely to abscond (Chase, 1975, chap. 8).

Although there is little or no relationship between *individual* patient characteristics and their perceptions of the social climates of their treatment programs, the *aggregate* characteristics of patient populations may be related to differences in social climate among treatment settings. However, relationships between aggregate personal and behavioral characteristics and the aggregate social climate cannot be generalized to individuals in any particular setting. Thus, for example, the fact that programs with more disturbed patients have less emphasis on autonomy (Moos, 1974) does not necessarily mean that *within* one program, the more disturbed patients will perceive less emphasis on autonomy than the less disturbed patients.

The present findings demonstrate that *within* programs, personal attributes of patients are only minimally associated with their environmental perceptions. Considered in conjunction with previous research, the results indicate that indices of perceived climate are not simply measures of background or psychosocial characteristics of the perceivers. However, there may be substantial differences in how different individuals perceive the same environment, and it is important to clarify the reasons for these differences. Characteristics of peoples' functioning or performance in an environment might be fruitful to investigate in this regard.

Effect of Psychotomimetics (LSD and Dextroamphetamine) on the Use of Primary- and Secondary-Process Language

Michael Natale
Department of Psychiatry
Columbia University

Charles C. Dahlberg
William Alanson White Institute
New York City

Joseph Jaffe
Department of Psychiatry, Columbia University and New York State
Psychiatric Institute, New York City

The present study sought to determine the effect of psychotomimetics (LSD and dextroamphetamine) on primary-process and secondary-process language. Five-minute monologues were recorded for four psychoanalytic patients in LSD, dextroamphetamine, and placebo conditions. An intensive research design was adopted, and each subject was treated as an individual experiment: (a) One patient manifested LSD-induced attenuation of secondary-process language; (b) one patient showed LSD-induced increase of primary-process language and an increase of secondary-process language when dextroamphetamine was ingested. The present findings suggest that psychotomimetics do affect ego functioning as expressed in language but that the nature of the effect (inhibition or disinhibition) is not determined by the drug alone.

It has been postulated that psychotomimetics (LSD, Ditrán, psilocybin) have certain consistent effects on verbal behavior. Gottschalk and Gleser (1964) found that LSD, psilocybin, and Ditrán promote disorientation and the use of denial language (subscale of Schizophrenia scale). Fink (1974) claims that psychotomimetics, such as dextroamphetamine, Ditrán, and LSD cause a decrease in "defensive language" (denial and disorientation). The contradictory nature of these findings may be the result of the fact that Gottschalk and Gleser's results were obtained from normals, and Fink's data were obtained from psychotic depressed patients who had received electric shock.

In light of the above-described "state of knowledge," the purpose of the present study was to verify the effects of psychotomimetics on

ego functioning as expressed in language use. "Pre-drug" and "post-drug" 5-minute monologues were recorded for four psychoanalytic patients (Jaffe, Dahlberg, Luria, & Chorosh, 1973) in LSD (50-100 mg), dextroamphetamine (15 mg), and placebo conditions. Each patient participated in 6-9 sessions for each drug condition, and an "intensive research design" was adopted, with each patient being treated as a separate experiment. Each monologue was transcribed, key-punched, and analyzed by Martindale's (1973) "count" program, which tabulates the percent frequency of words that belong to primary-process or secondary-process language categories. The results were as follows: (a) One patient manifested a significant attention of secondary-process language when under the influence of LSD, $t(7) = 2.48$, $p < .05$, two-tailed, with no significant placebo effect. (b) One patient showed a significant increase of secondary-process vocabulary when under the influence of dextroamphetamine, $t(8) = 3.07$, $p < .05$, two-tailed, and a significant increase in primary-process language after having taken LSD, $t(5) = 2.58$, $p < .05$, two-tailed, with no significant placebo effect. (c) Two patients manifested no drug or placebo effects. The present and previous findings suggest that psychotomimetics do affect ego functioning, as expressed in language, but that the nature of the effect (inhibitory or disinhibitory) is not determined by the drug alone.

This research was aided in part by National Institute of Mental Health Grant MH 13579, which supported the first author as a postdoctoral research fellow in the Interdisciplinary Research Training Program, Department of Psychiatry, Columbia University.

The authors wish to express thanks to the William Alanson White Institute where the project was originally conducted.

Short Forms of the MMPI with Back Pain Patients

Judith Turner
University of California, Los Angeles

Charles McCreary
Department of Psychiatry
University of California, Los Angeles
School of Medicine

This study compared the Faschingbauer abbreviated Minnesota Multiphasic Personality Inventory (FAM) and the Midi-Mult on a sample of 176 back pain outpatients. Correlations with the standard MMPI scales ranged from .67 to .93 ($M = .84$) on the FAM and from .71 to .89 ($M = .80$) on the Midi-Mult. The FAM showed higher agreement with MMPI code types than did the Midi-Mult. Finally, the three versions were compared to independent physician ratings of amount of functional component to patients' pain, and all three forms discriminated between "functional" and "organic" patient groups. The results provide tentative evidence that abbreviated MMPIs are useful measures of personality in this population.

A number of short forms of the Minnesota Multiphasic Personality Inventory (MMPI) have been constructed in attempts to produce an instrument that gives the same information but with much less time required of the respondent. The present investigation addressed the issue of the utility of two of these short forms—the Midi-Mult (Dean, 1972) and the Faschingbauer abbreviated MMPI (FAM) (Faschingbauer, 1974)—in a university hospital outpatient orthopedic clinic.

The standard form of the MMPI was administered to 186 male and female outpatients (M age = 44 years) who were seen at the Back Clinic. Each answer sheet was scored for the standard MMPI, Midi-Mult, and FAM scales except that 10 MMPIs were excluded because more than 30 items had been left unanswered. Ratings by the examining physician as to the amount of functional component to the patient's pain were recorded for 64 patients at the time of the patient's first visit to the Back Clinic and were made without knowledge of the patient's MMPI performance.

MMPI profiles were called invalid according to these rules: $F > 16$ and $F - K > 11$ raw score points. These rules were applied separately for the three versions. Two percent of the MMPIs were found to be invalid, whereas 5% of the FAM profiles were invalid, including 75% of the invalid MMPI profiles. None of the Midi-Mult profiles were invalid, showing a 100% error rate in iden-

tifying invalid standard MMPI profiles. The four standard MMPI profiles found to be invalid were excluded from further analysis of data.

Midi-Mult scale scores correlated with corresponding standard MMPI scale scores from .69 to .89 ($M = .80$). Correlations between FAM and full MMPI scales ranged from .67 to .93 ($M = .85$). The FAM was more highly correlated with the full MMPI than was the Midi-Mult on all clinical scales except Hypochondriasis, whereas the Midi-Mult was more highly correlated with the standard form on F and K .

Next, code-type agreement between the standard MMPI and the two short forms was examined. On a two-point code type comparison, the FAM was found to have 34% agreement with the long version in the same order and 43% agreement regardless of order. The Midi-Mult showed 22% agreement (same order) and 32% (any order). Less agreement resulted when three-point codes were compared (FAM: 14% same order, 31% any order; Midi-Mult: 9% same, 20% any).

Finally, comparisons were made between standard MMPI, FAM, and Midi-Mult profiles and independent physician ratings of the amount of functional component to patients' pain. Patients judged by physicians to have a very large functional component ($n = 39$) had standard MMPI scores that were significantly higher than those of patients judged to have little functional component ($n = 25$) on the K , Hypochondriasis, Hysteria, Schizophrenia, and Social Introversion scales ($p < .05$) and Psychopathic Deviate scale ($p < .01$). A similar pattern of differences was shown by the FAM, except that there were no significant differences between "functionals" and "organics" on the K and Psychopathic Deviate scales, whereas

Requests for reprints and for an extended report of this study should be sent to Charles McCreary, Department of Psychiatry, University of California, Los Angeles, School of Medicine, 760 Westwood Plaza, Los Angeles, California 90024.

the "functional" patients scored significantly higher on the Depression and Psychasthenia scales ($p < .05$). The Midi-Mult also showed a pattern of differences similar to the MMPI, except for no significant difference on the K scale and significant differences on Depression, Paranoia, and Psychasthenia ($p < .05$).

That both short forms were found to discriminate between "functional" and "organic" back pain patients is encouraging evidence that these measures may be useful with this population. Since the FAM, in particular, was shown to provide a

very good estimate of standard MMPI scores, further attention seems warranted in the direction of its use in such a setting.

Practicing A and B Psychotherapists' Responses to Schizoid and Neurotic Patient Prototypes

William B. Goodwin, Donald M. Quinlan, and Jesse D. Geller
Yale University and Yale School of Medicine

Eighty-three practicing male psychotherapists completed the A-B scale, responded to recordings of schizoid and neurotic patient prototypes, and rated their subjective reactions to each type. Multivariate analysis revealed a significant ($p < .013$) overall A-B Type \times Patient Type interaction. Although liking and ease of responding were higher in therapist-patient dyads, which the literature suggests are effective (A-schizoid, B-neurotic), felt compatibility and desire to work with the patient were higher in the opposite ("mismatched") dyads. These results suggest that subjective reactions underlying the A-B interaction effect are complex and that therapists respond in a differentiated, not global, fashion.

The A-B therapist "type" distinction originated by Whitehorn and Betz (cf. Betz, 1967) is an intriguing but conceptually elusive variable associated with a differential therapeutic aptitude. Based on items from the Strong Vocational Interest Blank reflecting activities mostly technical, mechanical, or manual in nature, the A-B scale differentiated therapists more effective with schizophrenics (As) from those less effective (Bs). McNair, Callahan, and Lorr (1962) later found Bs to be more effective with neurotic outpatients, giving rise to the "A-B interaction hypothesis" that As and Bs are differentially effective with schizophrenic and neurotic patients, respectively. Owing to the lack of clinical studies with the requisite factorial design, the interaction hypothesis has not yet been fully evaluated, although one such study appears to provide support (Berzins, Ross, & Friedman, 1972).

Experimental studies using schizoid and neurotic patient stimulus materials have given rise to contradictory findings regarding therapists' subjective reactions, however. Although Kemp (1966), for example, found a "paradoxical discomfort" on the part of As with schizoid "patients" and Bs with neurotic patients, Berzins and Seidman (1968) failed to replicate. As a whole, such analogue studies have lacked realism in numerous respects: in the nature of the patient stimuli, in the mode of response, in the social context, in the physical setting, and in the

sample of subjects used as "therapists." Further, the impact of therapist experience level on the A-B variable has not been evaluated. Our primary aim was to extend findings of subjective reactions of A and B undergraduate "quasi-therapists" to a sample of practicing A and B psychotherapists, using the experimental analogue approach.

Eighty-three out of 136 practicing male psychotherapists with at least 1 year of experience completed the Schiffman, Carson, and Falkenberg (Note 1) 23-item version of the A-B scale. The 20 highest scoring (A) and 20 lowest scoring (B) therapists were presented realistic audio recordings of avoidant of others (schizoid) and turning against self (neurotic depressive) patient prototypes used by Berzins and Seidman (1968), listened to five 1-minute segments of each patient in the privacy of their own offices, and spoke their responses—which could include interrupting the patient or silence—into a cassette recorder. Order of presentation of prototypes was counterbalanced across therapists. After each 5-minute segment, therapists completed a six-item questionnaire assessing subjective reactions to the patient.

Results

A four-factorial multivariate analysis of variance (Therapist Type \times Experience Level \times Patient Type \times Order) yielded a significant ($p = .013$) Therapist Type \times Patient Type interaction. The standardized discriminant function coefficients weighted the six components as follows: (a) desire to work with the patient, -1.165 ; (b) ease of responding, $.832$; (c) lik-

ing, .816; (d) felt compatibility, $-.328$; (e) felt comfort, $.171$; and (f) satisfaction with spoken responses, $-.137$. Two univariate analyses of variance revealed trends for reversed Therapist Type \times Patient Type interactions: Higher scores were obtained for "mismatched" (B schizoid, A neurotic) therapists on desire to work with the patient ($p = .055$) and felt compatibility ($p = .09$). No significant main effects were found nor were there any significant interactions with experience or order of presentation.

Discussion

Broadly summarized, although these therapists felt it easier to respond to and like the "matched" patient better, they felt more compatible with and preferred to work with the mismatched patient. These results offer support for the hypothesis that A and B psychotherapists can be differentiated by their subjective reactions to schizoid and neurotic patients. The direction and meaning of these differences is complex.

Previous investigators have hypothesized that failures of therapeutic communication can result from resemblances between patient defense mechanisms and therapist coping style, and that there are certain personological similarities between Bs and schizoids and possibly between As and neurotic depressives (e.g., Berzins, Seidman, & Welch, 1970). Taken together, these considerations suggest that (a) therapists may equate similarity with compatibility and therefore prefer to work with patients because they perceive them as similar, hence compatible or (b) if therapists are aware of their limitations with mismatched patients, their preferences may reflect a desire to grapple with and overcome their "blind spots" by means of massed practice. There is some suggestion (Goodwin, in press) that inexperienced B therapists do see a higher proportion of schizoid patients than inexperienced As. If this is a replicable finding, the possibility that B (and/or A) therapists increase their clinical effectiveness with mismatched patients as they gain experience needs empirical study. A third explanation for the present findings is that some degree of felt incompatibility is more favorable to therapeutic outcome.

If all of the subjective reactions—liking, ease of responding, felt compatibility, and so on—

showed the same pattern of higher scores for matched dyads, we might have speculated that there is a simple underlying affective dimension describable as "good vibrations." However, the different signs of the discriminant function coefficients and the contrasting patterns of means indicate that the subjective *alternative* reactions underlying the A-B interaction effect are complex, and that more broadly, therapists' reactions to patients are differentiated rather than unidimensional. Finally, how therapists use such feelings—"countertransference" or otherwise—as a data base from which to formulate therapeutic responses is a question that deserves empirical study.

Comparisons of Rating Scales of Child Psychopathology in Clinic and Nonclinic Samples

Susan B. Campbell

McGill University and the Montreal Children's Hospital

Yvonne Steinert

Jewish General Hospital
Montreal, Canada

Mothers of 45 control and 35 clinic children completed two factor-analytically derived rating scales of child psychopathology, the Behavior Problem Checklist and the Parent Questionnaire. Intercorrelations among factors indicated some factor overlap and some differences between apparently similar factors. Conduct problem ratings on the Behavior Problem Checklist covaried with ratings of conduct problems, hyperactivity, and learning problems on the Parent Questionnaire. Patterns of correlations suggested that mothers of nonreferred children rated pathology *per se*, whereas mothers of referred children rated behaviors that fell into internalizing and externalizing clusters. Teachers asked to rate 22 referred and 22 control children on the Behavior Problem Checklist and the Teacher Rating Scale showed more consistency in the behaviors rated. Although similar factor labels are used from scale to scale, they reflect somewhat different behaviors and are influenced by the child's clinical status, the rater's past experience with children, and specific scale characteristics.

The Behavior Problem Checklist (Quay & Peterson, Note 1), the Parent Questionnaire (Conners, 1970), and the Teacher Rating Scale (Conners, 1969) are factor-analytically derived instruments based on common descriptors of child psychopathology. They are widely used in epidemiological, diagnostic-descriptive, and outcome studies with child populations (Quay, 1972). However, despite overlap and variation in both item content and factor labels, it is unclear how the factor scores covary.

Content analysis suggests that different behaviors are covered by the same factor label and similar behaviors by different labels from scale to scale. Thus, all include a conduct problem factor reflecting discipline problems and defiance of authority. While one scale also includes hyperactive behavior under this rubric, the others isolate it as a separate factor. Likewise, all include a neurotic factor with items about fears and worries but differing in emphasis on social withdrawal and low self-esteem. Thus, the present study provides data on the relationships among those factors with overlap in content and/or label. Several factors on

the Parent Questionnaire that load on only a few items and are infrequently rated were excluded, as was the socialized delinquency factor on the Behavior Problem Checklist, which has little relevance with younger age groups.

Forty-five control and 35 clinic children (M ages = 7.6 and 7.5) took part in this study. Non-clinic subjects were at grade level and had never received psychological help. Clinic subjects were perceived as inattentive and poor school achievers with a variety of additional behavior problems. There were five girls in each group. All children were of at least average IQ, from lower middle to middle class, and in kindergarten through Grade 4 in school. Mothers completed both the Parent Questionnaire and the Behavior Problem Checklist by rating a series of statements as no problem, a mild problem, or a severe problem. In addition, six classroom teachers completed the Behavior Problem Checklist and the Teacher Rating Scale on a similar and partially overlapping sample of 22 clinic and control boys (M ages = 8.3 and 8.5).

Factor scores on the two scales completed by mothers were correlated for clinical and control groups separately. Similar analyses were carried out on teacher ratings. Data are summarized in Table 1. Ratings of clinic children by mothers suggest consistency between scales in that conduct problems, learning problems, and hyperactivity all intercorrelated, indicating a cluster of externalizing behaviors. It appears from the pattern of relationships that conduct problems as measured by the Behavior Problem Checklist include discipline

* $p < .05$.

** $p < .01$.

*** $p < .001$.

problems, attentional difficulties, and dislike of school. Similarly, immaturity, anxiety, and personality problems are interrelated, indicating a cluster of internalizing symptoms, with the anxiety factor including behaviors measured by both the immaturity and personality problem factors. Psychosomatic complaints are relatively independent of other factors. Although control mothers' ratings form similar patterns, additional correlations between internalizing and externalizing factors, for example, conduct problem and anxiety, suggest that they are rating a more heterogeneous array of pathology rather than behaviors that cluster into "neurotic" or "acting out" forms of pathology. Thus, the distinction between internalizing and externalizing symptoms appears more evident in the context of either recognized pathology or a larger number of deviant behaviors.

Teacher ratings form similar patterns of correlations for both groups. Thus, inattentive and hyperactive behaviors show strong relations to conduct problems. However, conduct problem ratings appear to reflect somewhat different behaviors in control and clinic groups. Teachers appear to be rating primarily fidgety, impulsive, and restless behavior in the control group, whereas conduct problem ratings in the clinic group appear to also reflect discipline problems. Moreover, teachers, who have experience with a large number of children, appear to group internalizing and externalizing behaviors intuitively whether they are rating clinic

or control groups, something not evident in the ratings of control mothers.

These data indicate that behaviors considered indicative of child psychopathology differ in patterning as a function of the child's clinical status and with the experiences of the rater. In addition, there is evidence that these scales measure both overlapping and distinctive aspects of behavior problems. This appears to be the case even for factors with the same name. Thus, studies that define samples on the basis of high scores on factors such as conduct problem or anxiety need to consider differences among scales as well as characteristics of raters and subjects.

Buss-Durkee Assessment and Validation with Violent Versus Nonviolent Chronic Alcohol Abusers

Gisele J. Renson, John E. Adams, and Jared R. Tinklenberg

Department of Psychiatry and Behavioral Sciences, Stanford School of Medicine,
and Veterans Administration Hospital, Palo Alto, California

Twenty-six chronic alcohol abusers who had been violent while intoxicated and 25 nonviolent alcohol abusers were administered the Buss-Durkee Inventory. All subjects were Caucasian men with a reported daily intake of ethanol of $227 \text{ ml} \pm 89 \text{ ml}$ for at least the last 5 years. Violence was documented by police records and by patient and family reports. Violent drinkers scored significantly higher than control subjects on the inventory Total Hostility score and on subscales measuring Assault, Irritability, Verbal Hostility, Indirect Hostility, and Resentment.

The earliest hostility inventories developed during the late 1950s, with few exceptions (Schulz, 1954; Zaks & Walters, 1959), consolidated various aggressive behaviors into a single omnibus score (Buss, 1961). Buss and Durkee (1957) developed subclassifications of overt and covert hostility. Normative data for this inventory have been reported by Buss (1961) for adult normal and psychiatric populations and by Morrison, Chaffin, and Chase (1975) for normal adolescents. The present study attempted to validate the Buss-Durkee as an inventory of hostility and to provide normative data for a population of violent and nonviolent alcohol abusers. We hypothesized that the Buss-Durkee Inventory would discriminate between these two groups and that overt hostility would be higher in the scores of alcoholics who became violent while intoxicated.

The experimental subjects were 26 Caucasian men ($M \text{ age} = 37 \pm 10$), who were seen as outpatients at the Alcohol and Violence Clinic of the Stanford University Department of Psychiatry and Behavioral Sciences. All of these subjects had demonstrated alcohol abuse, and virtually all (25 of 26) had demonstrated violent behavior only

while intoxicated. A control group of 25 Caucasian men ($M \text{ age} = 43 \pm 9$) was selected from the Stanford Inpatient Service for alcohol abusers at the Palo Alto Veterans Administration Hospital. None of the control subjects had demonstrated violence while intoxicated.

All subjects were screened by one of the authors and at least one other member of the Stanford psychiatric staff to exclude patients with neurological disorders or history of other forms of drug abuse. Experimental and control groups were matched for age, education, occupational level, and alcohol consumption. The majority of subjects in both groups were unskilled or semiskilled workers (65% of the experimental and 72% of the control subjects), according to the Hollingshead (Note 1) classification. All subjects had had a daily ethanol consumption of $227 \text{ ml} \pm 89 \text{ ml}$ for the past 5 years or more, and most had begun drinking heavily in their late teens (16 ± 3 years).

Experimental subjects had police-documented histories of violence while intoxicated. Twenty-four experimental subjects had documented physical assaults against others. Both of the remaining experimental subjects had histories of verbal hostility toward their families. In addition, one had threatened his wife with a deadly weapon and the other had a police record for destruction of property.

Within the first 2 weeks of admission to treatment, each subject completed and signed the Buss-Durkee Inventory under the staff psychologist's supervision. All subjects were assured complete confidentiality.

The Buss-Durkee Inventory (Buss & Durkee, 1957) is a self-rating scale of 75 true-false items based on the rationale that hostility can usefully be divided into seven subgroups or scales: (a)

Table 1
Buss-Durkee Inventory Scores of Violent
(Experimental) and Nonviolent (Control)
Alcohol Abusers

Scale	Experimental ^a		Control ^b		<i>t</i>
	<i>M</i>	<i>SD</i>	<i>M</i>	<i>SD</i>	
Total Hostility	36.58	9.07	28.64	9.40	3.07**
Assault	6.15	2.33	4.40	1.76	3.02**
Indirect					
Hostility	5.54	1.79	4.36	2.00	2.22*
Irritability	6.88	2.45	4.92	2.56	2.79**
Negativism	2.35	1.23	2.48	1.60	.33
Resentment	3.32	1.86	2.60	2.00	1.33*
Suspicion	3.88	1.77	3.28	2.30	1.05
Verbal					
Hostility	8.58	2.76	6.36	2.58	2.96**
Guilt	5.12	2.53	5.58	2.62	.64

^a *n* = 26.

^b *n* = 25.

* *p* < .05.

** *p* < .01.

Assault or direct physical violence against persons; (b) Indirect Hostility either against persons, through gossip or practical jokes, or against objects, such as slamming doors or breaking things; (c) Irritability or explosiveness and exasperation at the slightest stimulus; (d) Negativism as either active rebellion or as passive compliance to rules and authority figures; (e) Resentment, anger, jealousy, and/or hate of others due to real or imaginary mistreatment; (f) Suspicion, varying from distrust to projections of hostility onto others and the belief that these others are derogatory and harmful; and (g) Verbal Hostility in style or content. These seven scales yield a Total Hostility score. There is also a Guilt scale, which is independent of the above.

Table 1 shows the scores obtained by the control and experimental groups. The Total Hostility score reveals that violent alcohol abusers scored significantly higher ($p < .01$) than the nonviolent group. A more refined presentation of the kinds of hostility experienced by the subjects is reflected in the subscale scores. Violent alcoholics scored significantly higher ($p < .01$) on the scales measuring Assault, Irritability, and Verbal Hostility, and also ($p < .05$) on Indirect Hostility and Resentment. The two groups did not differ significantly on Negativism, Suspiciousness, or on the Independent Guilt scale.

The data were analyzed for any relationship between age, individual scores, and/or Total Hostility score. Both groups were divided into younger (up to 40 years) and older (40 years and above) subjects. A linear regression procedure showed no relationship between age and any scores for the control subjects. For the experimental subjects, an age effect was shown for the Suspicion scale only, which tended to decrease with age ($p < .05$). The five most verbally aggressive subjects were compared with the five least verbally aggressive subjects in each group to assess whether subjects with higher verbal aggressiveness scores tended to have lower assaultiveness scores. This was not found to be the case; subjects with higher verbal aggressiveness scores did not have lower assaultiveness scores. All subjects had high scores on the Assault scale.

Our findings show a positive correlation between violence while intoxicated and Buss-Durkee Inventory scores on Total Hostility as well as five of seven hostility subscales among two groups of alcohol abusers. This confirms the validity of the Buss-Durkee Inventory as a measure of hostile feelings and aggressive behavior in this sample and suggests that the Buss-Durkee Inventory may be useful in assessing potential for violence in alcohol abusers.

On the Word Preferences of Suicidal Versus Nonsuicidal College Students

Steven Thurber and David P. Torbet
Boise State University

A word preference format was used to investigate reactions to verbal stimuli of suicidal and nonsuicidal persons. Six words with either aggressive or submissive denotative meanings significantly differentiated the two groups. In addition, the word *suicide* was selected at a higher frequency level by suicidal individuals when compared to their nonsuicidal counterparts.

Jung (1918) and Luria (1932) were notable among several early clinicians who investigated the premise that affective reactions to verbal stimuli might yield information as to personality characteristics and motivational states. The traditional approach was to base clinical inferences on the denotative meaning of words eliciting high levels of emotionality as judged by physiologic indicators (e.g., skin resistance; changes in breathing). More recently, affective arousal (or what has since been termed *reinforcement value*) has been assessed by ratings on a like-dislike continuum (Rychlak, 1966) or by noting word preferences in a series of paired associates (Torbet, Note 1).

The present study was designed to see whether suicidal individuals could be distinguished from a nonsuicidal group on the basis of word preferences. The participants were 21 persons referred to a university counseling center following documented instances of attempted suicide (2 of these individuals were later successful in suicide attempts). They were compared to students from general psychology classes controlling for age ($M = 25.9$) and sex (13 females; 8 males). The subjects selected the most preferred word for each of 233 word pairs. Randomly distributed among these items were six words expected to elicit differential reactions from the *a priori* groups. They included the words *murder*, *kill*, *attack*, *submit*, *suicide*, and *martyr*. Together, they formed 30 word pairs, and in accord with circular unfolding scaling procedures they constituted an undimensional metric scale or what was termed an *aggressive-*

submissive dimension (Cooper, 1971). Following the designation of preferences across all items, the frequencies within this dimension were tallied, with each word having a possible score of 5.

Wilk's lambda criterion indicated that the equality of mean vectors for the two groups was untenable, $\chi^2(6) = 17.96$, $p < .006$. Univariate analyses indicated that the suicidal group showed a significantly higher preference for suicide ($M = 3.76$ vs. $M = 1.90$), $t(20) = 4.47$, $p < .001$, whereas the nonsuicidal subjects significantly preferred attack ($M = 3.38$ vs. $M = 2.62$), $t(20) = 2.61$, $p < .01$.

A linear discriminant analysis yielded a canonical correlation of .62. The primary contributor to the discriminant function was suicide, with a standardized coefficient of 1.29 followed in order of magnitude by submit (.56), martyr (.52), kill (.48), murder (.29), and attack (.02). Evidence for the discriminating ability of the word scale is shown in the finding that 34 of the 42 participants (81%) were correctly classified into suicidal and nonsuicidal categories on the basis of discriminant scores.

The results suggest the potential clinical utility of a word preference technique in the assessment of suicidal probabilities. The denotative meanings of the stronger discriminating variables support the notion that attempted suicide may represent a surrendering to hostile impulses by turning them toward oneself in an intropunitive manner (Kisker, 1964). Finally, the data suggest that the word *suicide* has reinforcement value for those with suicidal inclinations.

Role of Locus of Control in Frustration-produced Aggression

Kiran Bhatia and Sanford Golin
University of Pittsburgh

This experiment tested the hypothesis that external locus of control subjects would exhibit greater frustration-produced aggression than internal locus of control subjects. Incorrect responses by a frustrating or nonfrustrating confederate were punished by electric shock. Analysis of the shock data indicated increased aggression after frustration by externals and less aggression by internals. The results support the hypothesis and indicate that aggression is cognitively regulated by a personality-related belief in uncontrollability; the less the believed control, the greater the aggression.

This experiment was concerned with the cognitive control of frustration-produced aggression. According to one view (e.g., Geen, 1972), frustration results in aggression when it increases arousal in the presence of cues associated with aggression. Recent reports indicate that the extent to which frustrating events are perceived as aversive and thereby increase arousal is a function of the extent to which such events are perceived as controllable (Donnerstein & Wilson, 1976; Glass & Singer, 1972). Perception of controllability is related to the characteristics of the particular situation in which frustration occurs. Such perception, however, may have personality as well as situational determinants. Specifically, one's locus of control (see Phares, 1976), that is, transsituational beliefs about one's ability to exercise control over outcomes, may influence the extent to which frustration results in aggression. Those who generally do not believe they can control outcomes (external locus of control) are expected to exhibit greater aggression in response to frustration than those who generally believe they can control outcomes (internal locus of control). The present experiment tested this hypothesis.

Forty-eight internal locus of control and 48 external locus of control subjects were equally divided into frustration and nonfrustration experimental subgroups. Using a standard procedure to measure aggression, subjects taught a confederate a task by punishing incorrect responses

with electric shock, which was ostensibly administered to the confederate. Shock durations and intensities were recorded as measures of aggression. Each subject was motivated to have the confederate learn the task as quickly as possible; the confederate learned relatively poorly in the frustration condition and relatively well in the nonfrustration condition.

An analysis of variance of shock duration data showed a Locus of Control \times Frustration interaction, $F(1, 88) = 5.86, p < .05$. Scheffé's test ($p < .05$) showed that the mean shock duration of frustrated externals ($M = .65$ sec) was greater than the means of nonfrustrated externals ($M = .49$ sec) and frustrated internals ($M = .50$ sec). Frustrated internals showed less aggression than nonfrustrated internals ($M = .58$ sec), but this difference was not significant. As predicted, therefore, frustration resulted in increased aggression for externals but not for internals.

Analysis of the shock intensity data showed the mean intensity of frustrated internals ($M = 2.97$) to be less ($p < .05$) than that of nonfrustrated internals ($M = 4.37$). The mean intensity of frustrated externals ($M = 5.10$) was greater than that of nonfrustrated externals ($M = 4.32$), as predicted, but this difference was not significant.

The prediction that externals would exhibit greater aggression in response to frustration was based on the view that aggression would be regulated by a generalized belief in uncontrollability. If, however, locus of control were considered to be a measure of a need to control, a motive said to be characteristic of internals (see Phares, 1976), then frustration should have been more aversive and arousing for internals than for externals. A prediction of greater aggression in response to frustration by internals follows from this perspective. Internals, how-

This article is based on a dissertation submitted by the first author in partial fulfillment for the PhD degree at the University of Pittsburgh.

Requests for reprints and for an extended report of this study should be sent to Sanford Golin, Department of Psychology, University of Pittsburgh, Pittsburgh, Pennsylvania 15270.

ever, showed reduced rather than increased aggression in response to frustration. Hence, the present results were not in accord with this motivational interpretation of locus of control.

In summary, the results showed that generalized expectancies about one's ability to control outcomes can influence aggression in response to frustration in a manner similar to that previously reported for situationally induced expectancies about controllability (Donnerstein & Wilson, 1976): The less the believed control, the greater the aggression.

Personality and Social Factors in Adolescent Marijuana Use: A Path-Analytic Study

Paul M. Kohn

York University, Downsview, Canada
and Addiction Research Foundation
Toronto, Canada

Helen M. Annis

Addiction Research Foundation
Toronto, Canada

Measures of the following variables were obtained from 193 high school students: marijuana use; attitude toward marijuana use; the peer-acceptance and symbolic-protest functions of marijuana use; sociopolitical outlook; and internal sensation seeking. Path analysis supported a model that assumes the following: (a) Only attitude affects use directly. (b) Both the peer-acceptance and symbolic-protest functions, as well as sociopolitical outlook, and internal sensation seeking influence attitude directly. (c) Sociopolitical outlook affects both functions directly. Support for the model came from very close correspondence between the observed and predicted correlations and the low, nonsignificant value of the overidentification test statistic.

This study evaluates a multivariate model of youthful marijuana use. The model assumes that use or nonuse reflects a person's attitude toward marijuana use, that is, his/her evaluative reaction to such behavior (cf. Fishbein, 1967a, 1967b). Attitude, in turn, depends on the perceived functions of marijuana use. Our model includes two functions: the symbolic-protest function or value of marijuana use for symbolizing disidentification with conventional society and the peer-acceptance function or the value of marijuana use for gaining acceptance from permissive peers. Also, the model incorporates two personality variables: general left-right sociopolitical outlook and internal sensation seeking, a propensity to seek satisfaction from fantasy, emotional change, and unusual perceptual experience (Pearson, 1970). Sociopolitical outlook should affect the symbolic-protest function because expressing disidentification with conventional society should appeal specifically to rather rebellious persons. Both personality factors should influence the peer-acceptance function because people's own attitudes and prac-

tices should predispose them to seek acceptance from similarly inclined peers (Byrne, 1971). Finally, both personality variables should affect attitude.

To test our model, we administered questionnaires to 96 male and 97 female high school seniors. The following measures were used: frequency of marijuana use over the past 6-month period; a brief, modified version of Wilson and Patterson's (1968) Conservatism Scale, which measures sociopolitical outlook; the Internal Sensation-Seeking subscale from a modified version of Pearson's (1970) Novelty Experiencing Scale (Kohn & Annis, 1975); and specially constructed measures for attitude to marijuana use, peer-acceptance function, and symbolic-protest function. All alpha or Kuder-Richardson 20 reliabilities were satisfactory, ranging from .76 to .91. In addition, the attitude and function measures in which all items referred to marijuana were shown to be factorially independent.

Path analysis, a multiple-regression procedure for testing the implications of causal models (Kim & Kohout, 1975), was applied to the data. The resultant path diagram appears in Figure 1.

The path diagram strongly resembles that implied by our model. The sole discrepancy is the absence of a significant path coefficient between internal sensation seeking and the peer-acceptance function. Possibly, internal sensation seeking is not publicly visible enough a trait to affect interpersonal attraction except in very close relationships. The residuals, symbolized by e_1 in Figure 1, express the square root of the unexplained variance for each dependent variable.

The authors gratefully acknowledge the assistance of Carol Watson and Judith Groeneveld in the various stages of data collection and analysis. They also appreciate the critical comments of Norman Endler, Michael Goodstadt, Igor Kusyszyn, and Reginald Smart on an earlier draft of this article and the advice of Michael Ornstein on path analysis.

Requests for reprints and for an extended report of this study should be sent to Paul M. Kohn, Department of Psychology, York University, Downsview, Ontario, Canada M3J 1P3.

Figure 1. Path analysis for marijuana use.

Thus, the model explains about 33% of the variance in marijuana use and about 45% of the variance in attitude. The overidentification test statistic (Land, 1973) proved nonsignificant, $L(6) = 4.00$, $.70 > p > .50$. This means that our model fits the data well. Further evidence of success comes from comparisons of the observed correlations with those predicted by the model through summing direct causal, indirect causal, and noncausal contributions (Kim & Kohout, 1975). Predictive errors were generally modest and in all cases nonsignificant. Finally, the results of separate path analyses conducted for each sex separately were highly similar.

In general and with the one exception noted, the results support our a priori model. The variance accounted for in attitude and behavior, about 45% and 33%, respectively, is high enough to support the importance of the predictors selected but low enough to suggest extending the model. For example, the present model overlooks the perceived dysfunction of the various health-related and social-legal risks ascribed to marijuana use and the related personality variable of risk-taking propensity. Also, longitudinal research permitting stronger causal inferences seems desirable. Work along both these lines is proceeding.

Weight Loss and Behavior Change 1 Year After Behavioral Treatment for Obesity

Robert W. Jeffery, Michael Vender, and Rena R. Wing
Stanford Heart Disease Prevention Program, Stanford University Medical Center

The study presents a 1-year follow-up of the first 108 clients to complete a behavioral weight reduction program at Stanford University's Eating Disorders Clinic. On the average, clients maintained their in-treatment weight loss over the follow-up period, but there was marked variability and a low correlation between in-treatment and posttreatment performance. Clients reported significant changes in their eating behavior after treatment, but these changes were only weakly related to weight changes.

Although behavioral treatments for obesity appear to produce favorable short-term results, results of follow-up studies have been weak (Stuart, 1975). Maintenance has typically been assessed over short time intervals (e.g., Hagen, 1974), and many studies suffer from small sample size or high attrition (e.g., Hall, 1973; Mahoney & Mahoney, 1976). In addition, although weight losses in behavioral programs are thought to be mediated by changes in eating behavior, there has been little research on the maintenance of new eating patterns.

The present article reports a 1-year follow-up of clients treated with behavioral techniques at the Stanford Eating Disorders Clinic (EDC), where maintenance of weight loss and behavior change are evaluated and related to the use of various weight control strategies.

Follow-up data for 88 of the first 108 clients to complete the weight control program at the EDC were derived from telephone interviews. Pretreatment weights averaged 257 pounds (116.8 kg) for males ($n = 16$) and 209 pounds (95 kg) for females ($n = 72$), with a range from 141 (64.1) to 353 pounds (160.5 kg). Time from completion of treatment varied from 12 to 18 months.

Treatment was conducted in small groups led by two experienced therapists, who met weekly for 1½ hours for 20 weeks. Lessons, presented in seminar format, covered the following topics

(Ferguson, 1975): self-monitoring, stimulus control, slowing the rate of eating, social support, exercise, diet, preplanning, and individual problem solving. Clients maintained daily records of their eating and exercise behaviors, which were checked weekly. All expenses were prepaid (\$250), and a 10% refund was given contingent on attendance and completion of homework assignments.

A subset of 25 clients completed a self-report questionnaire at the time of follow-up. In terms of demographic characteristics and weight loss, they were representative of the larger sample. They rated their eating behavior on 5-point scales at three points in time: before treatment, immediately after treatment, and currently. Twelve questions referred to behaviors taught in therapy (e.g., restricting the location of eating), 5 to thoughts about food (e.g., feeling guilty about eating), and 8 to specific eating problems (e.g., binge eating). Clients also rated the helplessness of 21 techniques presented in treatment and indicated whether each was used immediately after treatment and/or at present.

Clients lost an average of 12.8 pounds (5.8 kg) during the program and an additional .7 pounds (.3 kg) during follow-up. Ninety percent lost weight during treatment, and 43% lost additional weight during follow-up. However, weight losses by the end of follow-up were extremely variable, ranging from 80 pounds (36.4 kg) lost to 40 pounds (18.2 kg) gained. Both the percent of clients losing 20 pounds (9.1 kg) or more and the percent gaining weight more than doubled between the end of treatment and follow-up. Weight losses during follow-up were unrelated to weight losses during treatment ($r = .002$). Subject characteristics, such as sex and age of onset of obesity, were also unrelated to long-term success.

The present research was supported in part by National Institute of Mental Health Research Grant NH 26482-01 to Albert J. Stunkard.

Requests for reprints and for an extended report of this study should be sent to Robert W. Jeffery, Stanford Heart Disease Prevention Program, 730 Welch Road, Palo Alto, California 94304.

Clients reported substantial improvements in eating behavior during treatment. Twenty of the 25 questionnaire items showed significant positive changes. Although there was some deterioration during follow-up, improvements were still clearly evident in 19 items 1 year later.

Clients reported using an average of 9.4 of the 21 techniques immediately after the program, but only 6.6 by the time of follow-up, $t(22) = 3.16$, $p < .005$. The 21 behavioral techniques were grouped according to the eight topics presented in the program. In comparative analyses social support techniques were used significantly less than other techniques both immediately after treatment and at follow-up, $ts(22)$ ranged from 2.14 to 4.19, all $ps < .05$. Self-monitoring was rated significantly more helpful than any other technique, $ts(22)$ ranged from 3.28 to 5.92, all $ps < .01$. Only self-monitoring and preplanning did not decline in use significantly after treatment.

The relationship between behavioral variables and weight loss was weaker than expected. Weight loss was significantly correlated with only 5 of the 20 individual behaviors that changed during treatment and with 4 of 19 overall. Changes in thoughts about food were the best predictors of success.

Weight loss was modestly related to the reported use of behavioral techniques. Weight loss was significantly correlated with the use of self-monitoring ($r = .61$, $p < .01$) and situational restriction ($r = .47$, $p < .05$) immediately after treatment. In addition, those clients who used 11 or more techniques immediately after treatment lost more weight overall than those using fewer, $t(22) = 2.09$, $p < .05$. There were no significant relationships between weight loss and technique use at follow-up.

Weight loss following treatment in the EDC was similar to that reported in other investigations using self-control. The inability of clients

to lose additional weight on their own after behavioral treatments underscores the need for further study of maintenance processes. In the present program only 10% of the clients were within 20 pounds of their ideal weight a year after treatment and fully a third had enrolled in other weight loss programs. Almost all recommended continuing treatment contracts.

The failure to find strong relationships between self-reported behavior change and weight change, despite significant changes in eating habits, can be interpreted in several ways. Positive relationships may have been obscured by errors and biases in retrospective self-reports. Changes in eating behaviors may not be linearly related to changes in weight. Or, some clients may engage in idiosyncratic behaviors, such as traditional diets, that either enhance or retard their progress. Further research is needed to systematically assess the effects of specific changes in behavior on food consumption and weight.

Taylor's MMPI Correction Factor for Spinal Cord Injury: Empirical Endorsement

Philip C. Kendall
University of Minnesota

Jack Edinger
Virginia Commonwealth University

Carole Eberly
McGuire Veterans Administration Hospital
Richmond, Virginia

The Minnesota Multiphasic Personality Inventories (MMPIs) of 30 spinal-cord-injured (SCI) subjects, 30 hospitalized non-spinal-cord-injured controls (HC), and 30 hospital employee controls (EC) were studied here. MMPI items that significantly differentiated SCI subjects from controls were separately factor analyzed. The major factor resulting from the SCI-EC analysis was characterized by items of physical description, as was a similar SCI-HC factor. The SCI mean scale scores were then corrected for spinal cord injury by replacing the SCI response proportion for the factor-analytically identified physically descriptive items with the EC response proportion. This correction procedure was also done using Taylor's correction items. Both correction procedures resulted in significantly less pathological SCI scale means (1, 2, 3, 4, and 8). The present results support the notion that spinal cord injury can moderate MMPI item endorsement. Recommendations are discussed.

Taylor (1970) investigated the effects of spinal cord injury (SCI) as a moderator variable that affects the validity of the Minnesota Multiphasic Personality Inventory (MMPI) for persons with such injuries. Taylor contended that the physical disability affects the subject's test input by moderating the likelihood of a response endorsement and may substantially affect output and thus reduce the instrument's validity generalization. The extent to which the disability affects the MMPI is related to the number of items that the disabled patient responds to on a physically descriptive basis rather than a psychologically descriptive one.

Taylor's (1970) evaluation of SCI as a moderator variable compared the MMPIs of SCI patients with normal nonhospitalized cases and used the judgment of physical medicine special-

ists to identify items that appeared to be descriptive of the physical condition associated with spinal cord injury. Taylor then scored SCI MMPIs with a correction for the somatically relevant items (the physical descriptors). Removing the patient's response proportion for the somatically relevant items and substituting the nonpatient response proportion produced dramatic changes in profile elevation, configuration, and consequent interpretation.

Whereas Taylor (1970) used nine "specialists" to select the items that differentiated the SCI group from the nonhospitalized group, the present study intended to isolate those items that contribute to a physical rather than a psychological description by means of factor analysis. In addition, since one source of somatic concern in patients appears to be hospitalization, with its emphasis on symptoms and attention for physical difficulty, the present study includes a control for hospitalization composed of hospitalized non-SCI patients as well as nonhospitalized employee controls. Moreover, while Taylor's control group consisted of college students (average of 2 years more educated than the SCI group), the present nonhospitalized control group consisted of ward nursing aides with an educational level similar to the SCI subjects.

Three groups of male subjects, SCI ($n = 30$), hospitalized non-spinal-cord-injured subjects (HC; $n = 30$), and hospital employees (EC; $n = 30$),

Portions of this project were conducted while the first author was at Virginia Commonwealth University and the Palo Alto Veterans Administration Hospital. The authors wish to thank John Hugo for his assistance in the early conceptualization of the study and to Jeff Schulman for his assistance in data collection.

Requests for reprints and for an extended report of this study should be sent to Philip C. Kendall, Department of Psychology, Elliott Hall, 75 East River Road, University of Minnesota, Minneapolis, Minnesota 55455.

= 30) participated in the present study. The mean ages of the groups were, in the same order, 37.5, 43.4, and 37.3 years. Similarly, the mean educational levels of the groups were 11.8, 10.5, and 12.0 years. The overall mean age was 39.4 ($SD = 4.86$), and the overall educational level was 11.4 ($SD = 4.67$). Though the present groups were comparable, the present SCI group was 16.1 years older and 1.9 years less educated than Taylor's (1970) SCI group. Subjects in the present study individually completed the group form of the MMPI.

Chi-square analyses of the true-false response cells were conducted for each item in two comparisons (a) SCI-HC and (b) SCI-EC, resulting in 56 and 65 items, respectively. Similarly, Taylor reported 60 items that differentiated SCI from control groups.

Separate factor analyses were then conducted. The major factor resulting from the analysis of the items differentiating the SCI and EC groups was composed of 10 items (accounting for 26.1% of the variance) that gave a clear description of physical condition. Seven of these 10 items were among those identified by Taylor's specialists. A similar factor resulted from the analysis of the SCI-HC items, although it emerged second to a stomach-complaint factor and contained fewer items.

The SCI mean scale scores were then corrected using the EC response proportion for items factor-analytically identified and using Taylor's items. Both the factor-item-corrected and Taylor-item-corrected SCI profiles were significantly less pathological than the uncorrected SCI profiles on five scales (1, 2, 3, 4, and 8), but they remained significantly elevated when compared to the EC group profiles.

In general, the emergence of a physical description factor as the major component of

variance that distinguishes nonhospitalized patients from SCI subjects, and to a lesser extent the similar factor from the SCI-HC items, supported the validity of both (a) the items selected in the Taylor study and (b) the nature of physical condition as a moderator variable. In the present study, the factor-identified correction items (i.e., 273, 330, 9, 192, 63, 310, 51, 179, 20, 62) and Taylor's items resulted in significant reductions of the MMPI scale means (see above) of SCI patients. Even though both procedures corrected for SCI physical description, the profiles were still significantly different from the EC group.

The present study, by using a more representative group of SCI patients, more appropriate controls, and a more objective item-identification procedure, supports Taylor's contention that SCI can moderate MMPI item endorsements. To remove the unwanted effect of physical description, it is recommended that the MMPI answer sheet be scored twice, once scoring the physical description items and once deleting them. As noted by Taylor (1970), "this method specifies the minimum and maximum limits for the patient on each of the affected scales" (p. 187). Moreover, it is recommended that the empirically derived (factor-analytically identified) items reported herein constitute the correction factor.

Meanings that Professionals Attach to Labels for Children

Charles F. Carroll
Yale University

N. Dickon Reppucci
University of Virginia

This study sought to identify relative meanings among professionals of three clinical labels for children—mentally retarded, emotionally disturbed, and juvenile delinquent—as well as an average or unlabeled choice. Forty regular classroom teachers and 32 mental health workers responded on two questionnaires designed to measure their reactions to these labels with nine questions concerned with expectations for the child's success in school and work, implications for treatment strategies, and motivation to work with the child. The labels conveyed clearly different relative meanings, and the two professional groups differed in a consistent fashion.

Recent discussion and research regarding the labeling of children (e.g., Hobbs, 1975) has pointed to undesirable consequences of labels, for example, that labels affect professionals and trainees negatively (Foster, Ysseldyke, & Reese, 1975). Nevertheless, labels continue in widespread use, since they facilitate both accountability for governmental funding and determination of eligibility for services. In addition, professionals in human service and education need shorthand methods of communicating with each other and appear to find current classification methods meaningful and helpful. The suggested use of more general labels, such as "children with special needs," is problematic not only because many more children could be so labeled but also because more general labels do not fill the governmental and professional needs just mentioned. Therefore, current labels are likely to persist, and research that focuses on questions such as the following becomes critical. What are the relative meanings attached to various labels? Is one label more positive than another? Does a label have different meanings for different professional groups?

The purposes of the present investigation were twofold: (a) to examine the relative meanings among professionals of nonlabeled or average children and three common labels for children—mentally retarded (MR), emotionally disturbed (ED), and juvenile delinquent (JD)—and (b) to determine what, if any, differences there are between teachers and mental health workers in

response to these labels. Meanings investigated included the professional's expectations for the child's success in school and work, implications for treatment and placement strategies, and motivation to work with the child. Teachers and mental health workers were studied because (a) both groups come into contact with children having a range of labels; (b) mental health workers frequently consult with teachers; and (c) children labeled by one group usually retain that label as they contact the other group.

Forty regular classroom (Grades 6-9) teachers from three middle schools and 32 mental health workers, including psychiatrists, psychologists, social workers and counselors, from four child guidance clinics and one mental health clinic participated in the study. The schools and clinics serve Connecticut areas of varied size, family income, and racial composition. Each subject completed a case study questionnaire and a labels only questionnaire. Subjects were first presented with the case study questionnaire, a *standard* six-sentence case study of a 13-year-old boy either untitled or titled with one of the three clinical labels, MR, JD, or ED. The same label, or no label, was repeated in the first sentence. Subjects answered on a 7-point scale (extremely negative to extremely positive) nine questions about the boy that reflected the three attitude areas mentioned above.

Ten teachers and eight mental health workers were randomly assigned to each of the four case study questionnaire conditions. The labels only questionnaire consisted of a repeated measures design; each subject was asked to answer the same nine questions in regard to a 13-year-old boy for each of the three clinical labels alone and for "average, without any of these prob-

Requests for reprints should be sent to N. Dickon Reppucci, Department of Psychology, Gilmer Hall, University of Virginia, Charlottesville, Virginia 22901.

lems." The first author administered both questionnaires in the subject's own work setting.

Where a significant F statistic was obtained from the least squares solution to analysis of variance ($\alpha = .05$), multiple comparisons were conducted by t test ($\alpha = .05$) or Newman-Keuls test ($\alpha = .05$ for the case study questionnaire; $\alpha = .01$ for the labels only questionnaire). On the case study questionnaire, teachers, in contrast to mental health workers, rated the children across all label conditions as less likely to finish high school, $F(1, 64) = 4.05$, $p < .05$, and less motivated to learn in school, $F(1, 64) = 4.56$, $p < .05$, and they rated themselves lower on both knowledgeable for working with the boy, $F(1, 64) = 5.40$, $p < .05$, and willingness to do so, $F(1, 64) = 6.96$, $p < .05$. Similar results were obtained on the labels only questionnaire. Teachers also rated themselves as less knowledgeable and less willing to work with all clinically labeled children as compared with the average, whereas the mental health workers rated themselves as less knowledgeable and willing only with the MR, being uniformly high for JD, ED, and average; knowledgeableness, $F(3, 210) = 13.29$, $p < .001$; willingness, $F(3, 210) = 14.24$, $p < .001$. Similar results were found regarding expectations for success at future skilled employment, $F(3, 210) = 4.06$, $p < .01$. On both questionnaires mental health workers were less approving of primarily special class placement than were teachers. For the case study questionnaire, $F(1, 64) = 3.59$, $p < .06$; for the labels only questionnaire, $F(1, 70) = 5.22$, $p < .05$. All differences for professional groups were statistically controlled for sex and age bias. In summary, labels had more negative effects for teachers than for mental health workers in the areas of professional motivation and expectations for the child's success. For mental health workers, however, MR had more negative effects than the other labels.

There were differences among the labels that were the same for the two professional groups. On the case study questionnaire, subjects reported themselves as less knowledgeable when the label MR was involved than when no label was indicated, $F(3, 64) = 2.87$, $p < .05$. The labels only questionnaire results ($df = 3, 210$, $p < .001$) indicated that subjects tended to view delinquents as less likely to finish high school ($F = 92.08$) and as less motivated to learn in school ($F = 83.35$). They also rated the JD and ED as most likely to have serious need for all

three treatments: help for his family ($F = 112.95$), someone to talk about his problems with ($F = 38.30$), and professional help to work out difficulties he has getting along with other people ($F = 52.58$). The MR were rated in the middle, and the average, lowest. There was one contradictory result in this area on the case study questionnaire: Subjects viewed the families of the MR as more in need of professional help than the families of the JD or unlabeled boys, $F(3, 64) = 3.19$, $p < .05$. Finally, on the question, "How approving are you of primarily special class placement for John?" on the case study questionnaire, the MR received more approval than the JD or unlabeled and the ED, though high, were not statistically differentiated from the other labels, $F(3, 64) = 3.64$, $p < .05$. On the labels only questionnaire, subjects rated the MR and ED highest, JD next, and average lowest, $F(3, 210) = 84.35$, $p < .001$. To summarize, professionals expressed less motivation to work with the MR, who were perceived as generally less in need of clinical services but likely candidates for special class placement. JDs were rated as low on expectations for success in school, usually as highly in need of clinical services but as inappropriate for special class placement. The ED were uniformly rated highly in need of clinical services and highly appropriate for special class placement.

Although sex differences were sparse, there were five significant ($df = 3, 210$, $p < .05$) Sex \times Label interactions on the labels only questionnaire. In essence, women were more positive than men regarding treatment for the clinically labeled children, especially the ED and JD (family help, $F = 2.77$; for talk about problems, $F = 3.19$; help in interpersonal relations, $F = 5.16$). At the same time, the women were less willing to work with the JD ($F = 3.05$) and more pessimistic about the MR finishing school ($F = 2.67$).

In conclusion, the present investigation focuses attention on three neglected aspects of the labeling of children: (a) Professionals attach different relative meanings to clinical labels, (b) teachers and mental health workers may respond differently to labeled children, and (c) professional groups may have different relative responses to common clinical labels. The study suggests that blanket indictments of a specific label may miss various subtleties that can only be determined by detailing different relative meanings of common labels. Moreover,

understanding differences between professional groups may be even more important, as children labeled by one profession frequently keep that label when they come into contact with members of other professional groups. Therefore, it is imperative to delineate both the beneficial and the negative aspects of different labels among various professional groups.

Effects of Anxiety and Sex on Neuropsychological Tests

Glen D. King, H. Julia Hannay, Bruce J. Masek, and Joan W. Burns
Auburn University

The effects of anxiety and sex on neuropsychological test performance were studied. Thirty male and 30 female right-handed subjects responded to the Finger Tapping (FT), Form Board (FB), and State-Trait Anxiety tests. The original cutoff points for brain damage on the neuropsychological tests resulted in numerous false positives. Females performed significantly slower on the FT than males, and for females, trait anxiety was negatively correlated with FT performance and positively correlated with time to complete the FB. The implications of these results for testing psychiatric patients are noted.

Neuropsychological tests to detect and locate brain pathology are being used increasingly by psychologists, especially in psychiatric clinics. Tests that are commonly used in neuropsychological test batteries include the Finger Tapping Test (FT) and the Form Board Test (FB). For the FT test, the subject taps an armature connected to a counter as fast as possible for 10 sec. The FB test requires that a blindfolded subject put 10 blocks of various sizes into their correct places on a formboard, first with one hand, then the other, and then both hands together. The total time across the three administrations is computed. The subject is asked to draw all of the shapes on paper in their spatial interrelationship after removal of the board. This yields a measure of memory (shapes remembered) and localization (number of correct shapes properly located).

After repeated experience with these tests in clinical and demonstration situations, we have noted that (a) performance differed by sex, but separate norms are not provided, and (b) anxiety appeared to predict poor performance. To test these notions, a study was designed using 30 male and 30 female right-handed college student volunteers with no history of brain pathology. Subjects were administered the State-Trait Anxiety Inventory and the FT and FB tests, with the order of FT and FB counterbalanced within each sex. Analyses revealed no test order effects.

The original cutoff points for brain damage (Reitan, 1955) resulted in numerous false posi-

tives across both sexes for all of the tests. However, when the performance of our subjects was compared to more recent normative data for these tests (Kløve, 1974; Vega & Parsons, 1967), we found that the number of false positives was substantially reduced.

In consideration of sex differences on FT, females ($M = 43.1$) tapped fewer times than males ($M = 47.5$) across hands, $F(1, 56) = 15.6$, $p < .01$, with the sex difference being much larger for the right hand than the left as indicated by a Sex \times Hand interaction, $F(1, 56) = 5.61$, $p < .05$. These results are inconsistent with previous data showing women to be superior on manual dexterity tasks (Maccoby & Jacklin, 1974) and warrant further study. Other comparisons for sex were not significant. Considering anxiety, there was a negative correlation between trait anxiety (A-Trait) and FT performance for females; the higher the A-Trait, the lower the number of average taps on FT ($r = -.41$, $p < .01$).

Similarly, for women only, A-Trait was positively correlated with time to complete the FB test using the preferred hand ($r = .38$, $p < .02$) and both hands together ($r = .34$, $p < .03$). It should be remembered that the subjects were college students. Only a few had clinically elevated anxiety scores, and anxiety seemed more prevalent among women than men. These results could underestimate the effects of anxiety on neuropsychological tests, especially when the tests are used with patients from a psychiatric population or with patients who suspect the presence of a serious neurologic disorder.

These results question the validity of these neuropsychological tests. For the tests to be valid, it appears that at least the FT needs to have separate norms for each sex. In addition,

high anxiety in women had a deleterious effect on their performance on the FT and FB tests. This relationship needs to be carefully considered when neuropsychological tests are administered to and interpreted for psychiatric patients and neurological patients who often have high anxiety levels. The sensitivity of other neuropsychological tests to anxiety and sex differences needs to be investigated.

Diversity Among Lower-Class Therapy Clients: A Comparison of Class IV and Class V Psychotherapy Recipients

Michael T. Nietzel, Matthew G. Hile, and Charles Y. Kondo
University of Kentucky

Demographic and treatment-relevant differences were studied among 73 lower socioeconomic class psychotherapy clients at a predominantly rural comprehensive mental health center. Data were drawn from the records of all adult (46 females; 27 males) psychotherapy cases initiated and terminated in a recent 15-month period. Results indicate several differences among Social Classes IV and V despite the literature's prevalent assumption of IV-V equivalency. In addition, sufficient heterogeneity exists among Class V clients to justify a partitioning of that class into two distinct subgroups. Class IV and Class V clients also differed on a global measure of final outcome.

A substantial literature has attempted to assess the influence of client socioeconomic status (SES) on the psychotherapeutic process. One prevailing opinion shared by much of this research is an assumption of homogeneity among lower-SES clients with regard to demographic and treatment-related variables. This assumption was examined in the present study.

Subjects were persons who presented themselves for outpatient treatment at a federally supported Community Mental Health Center in rural northeast Kentucky. All cases initiated and terminated within a 15-month period were examined, and clients classified as belonging to Class IV or Class V (Hollingshead, Note 1) were selected (excluding minors and persons in special programs). The final study group consisted of 73 cases (females, $n = 46$; males, $n = 27$); 95% of the sample was white.

Using Hollingshead's weightings, three distinct groups were obtained (SES IV, $M = 55.6$; SES V_A, $M = 63.8$; SES V_B, $M = 74.2$), which t tests indicated differed at the $p < .02$ level. This suggested that Class V clients might be differentiated in this manner in subsequent analyses.

Requests for reprints and for an extended report of this study should be sent to Michael T. Nietzel, Department of Psychology, University of Kentucky, Lexington, Kentucky 40506.

Seventy-three files were examined by three psychology graduate students who made committee decisions on data drawn from the records. Demographic variables were age, sex, location of residence, education, occupation, income, marital status, number of dependent children, and type of family. Treatment-related information included source of referral, diagnosis, treatment received, number of sessions and weeks in treatment, fee, person responsible for termination, and final outcome. Contrasts of interest were tested using the chi-square statistic.

Class IV and Class V (total) clients differed significantly on occupation ($p < .001$) but not on amount of education. Class V clients were less likely to be married than Class IV clients ($p < .06$), and, if married, they were less likely to have children ($p < .05$). No differences were noted between the two groups on other demographic variables. Class IV and Class V clients did differ significantly on final outcome of therapy ($p < .02$). Class IV clients were more likely to have terminated therapy prior to their therapists' recommendations, whereas clients from Class V were more likely either to have refused service initially or to have improved (therapist evaluation) at the time of mutual termination. No other treatment variables differentiated the two groups. Comparisons of Class IV clients with Class V_A and V_B persons evidenced the same trends and differences. In addition, Class V_B received the diagnoses of schizophrenia, personality disorder, or transient situational disturbance more frequently than Class IV clients ($p < .05$).

be defined by a locus of control score of 6 or below, the more externally controlled alcoholic by a score of 7 or above. Thus, some degree of standardization is permitted, and researchers can test the means of their samples with the mean of the large normative group. The use of this base also permits ready comparison among other subpopulations of alcoholics. It is only when the most meaningful subgroups of alcoholics are so normed that useful comparisons and needed generalizations will emerge.

Distinguishing Learning-Disabled and Emotionally Disturbed Children on the WISC-R

Raymond S. Dean
Arizona State University

This study concerned the isolation of distinctive Wechsler Intelligence Scale for Children-Revised (WISC-R) subtest patterns that would differentiate the performance of emotionally disturbed and learning-disabled children. A stepwise discriminant analysis was used to evaluate the subtest scores of 60 learning-disabled and a matched sample of 60 emotionally disturbed children. Four subtests of the WISC-R differentiated significantly between diagnostic categories. Learning-disabled children performed predictively poorer on the Block Design, Picture Arrangement, and Object Assembly subtests and higher on Vocabulary than their emotionally disturbed counterparts. These results are interpreted as a deficit in perceptual organization for children with specific learning problems.

A problem frequently encountered by the clinician is the differentiation of emotionally disturbed and learning-disabled children. With the publication of the Wechsler Intelligence Scale for Children (WISC; Wechsler, 1949) came many attempts to aid such diagnosis with subtest patterns. Despite this long-standing interest, studies dealing with diagnostic implications of WISC scores have been inconclusive.

A close scrutiny of past research dealing with characteristic WISC subtest patterns reveals certain methodological shortcomings. Of concern in the majority of studies is the univariate treatment of subtests that are multiple variates. As multiple measurements of the same individuals, subtests are interdependent and should not be split off and considered univariately. But rather, diagnostic subtest patterns would be more heuristically assessed using a multivariate procedure that considers subtests in combination. Another noteworthy concern in past research is the possible contaminating effects of inconsistently defined criteria in the selection of subjects (Dean, 1977).

The present analysis concerned the isolation of a distinct subtest pattern on the Wechsler Intelligence Scale for Children-Revised (WISC-R; Wechsler, 1974) that would discriminate between learning-disabled and emotionally disturbed children. In distinguishing between

groups, a stepwise discriminant analysis was used as a base for evaluating the predictive power of subtests. Such an analysis is used to statistically discriminate between two or more groups on the basis of a number of variables. In the present situation, groups were defined in terms of their diagnostic classification. Subtest data and IQ composites were used as the discriminating variables on which the present groups were expected to differ.

Method

The subjects were 120 Caucasian children from the Phoenix, Arizona, area who had been diagnosed by two experienced psychologists as either learning disabled or emotionally handicapped. The emotionally disturbed group, composed of 48 males and 12 females, displayed specific conduct disorders: aggressiveness, temper tantrums, anxiety states, and so forth. Moreover, the behavioral criteria proposed by Quay (1972) were used for selection. None of the children in this group was reported to have specific or generalized problems in learning. A comparable group of subjects diagnosed as learning disabled comprised the second group. The twofold basis for selection of this group was (a) the criterion recommended by Chalfant and Scheffelin (1969) for the identification of children with specific learning disabilities and (b) their goodness of match with children in the emotionally disturbed group. This match was performed with respect to sex, age (± 2 months), present grade placement, and socioeconomic status as determined by the occu-

pation of the family's major wage earner. Children in both groups ranged in chronological age from 6.4 to 13.6 years, with a mean of 10.06 ($SD = 3.17$) for the learning-disabled group and 10.13 ($SD = 3.21$) for the emotionally disturbed children.

Subjects were individually administered the regular subtests of the WISC-R during a 6-month period, which were scored in the usual fashion. Subtest scale scores, along with the WISC-R Verbal, Performance, and Full Scale IQ scores, were calculated for each child.

Results and Discussion

The discrepancy between the Verbal IQ and Performance IQ means for each diagnostic group was evaluated using a t comparison for dependent samples. This analysis showed the emotionally handicapped children to have a significantly higher Performance mean than that obtained on the Verbal scale, $t(119) = 16.88$, $p < .01$. The differences between Verbal and Performance IQs were not significant for learning-problem children. Hence, this finding supports the contention of Performance IQ superiority for acting-out children but not for those with learning problems, replicating the findings of Dean (1977). A 2 (sex) $\times 2$ (diagnostic group) multivariate analysis of variance was computed to test for equality of subtest and IQ composite means. The analysis revealed a significant multivariate F ratio for groups ($p < .01$). The multivariate F for sex and the Sex \times Group interaction was not significant. The significant diagnostic group multivariate F yielded significant univariate comparisons for the Block Design, $F(1, 118) = 8.43$, $p < .01$, and Object Assembly, $F(1, 118) = 5.31$, $p < .05$, subtests, with both favoring children in the acting-out group.

A stepwise discriminant analysis using the WISC-R subtests and IQ composites as discriminators was computed. The selection of variables included was based on the significance of the function as measured by overall multivariate F ratio with the addition of each variable. Using such a procedure results in the choice of an optimal set of discriminating variables.

Of the 14 possible variables, the Block Design, $F(1, 118) = 8.43$, $p < .01$, Vocabulary, $F(1, 117) = 9.45$, $p < .01$, Picture Arrangement, $F(1, 116) = 6.96$, $p < .01$, and Object Assembly, $F(1, 115) = 6.08$, $p < .01$, subtests added significantly to the amount of centroid separation between groups. The Wilk's lambda chi-square transformation showed this derived function of

variables to be highly reliable, $\chi^2(4) = 22.11$, $p < .001$.

The present results provide an interesting and somewhat unexpected view of children with learning difficulties when compared with children whose problems involve inappropriate behavior. In general, children diagnosed as learning disabled scored predictively lower on the Block Design, Picture Arrangement, and Object Assembly subtests and higher on Vocabulary than emotionally disturbed children. With the exception of Vocabulary, these subtests correspond to a WISC-R factor that Kaufman (1975) has interpreted as Perceptual Organization, and they involve visually guided motor activity. Prior evidence indicates that these subtests also require the capacity to overcome the embedding of an item from its surrounding context (Goodenough & Karp, 1961). In the main, then, children who were learning disabled appeared more field dependent in their performance on the WISC-R. This finding suggests a disturbance on the part of learning-problem children in perceptual integration, whereas children with behavior problems displayed more of a verbal deficit. Generally, learning-disabled children performed more adequately on tasks within the performance area that required verbal skills than those subtests that required nonverbal visual constructive abilities.

Application of Electromyographic Biofeedback to the Relaxation Training of Schizophrenic, Neurotic, and Tension Headache Patients

Frank X. Acosta and Joe Yamamoto
Department of Psychiatry and the Behavioral Sciences
University of Southern California School of Medicine

Stuart A. Wilcox
California State University, Los Angeles

This study examined the effects of electromyographic (EMG) biofeedback on tension reduction by schizophrenic, neurotic, and tension headache patients. Fourteen patients participated voluntarily in at least 10 weekly EMG biofeedback sessions at a public outpatient clinic. All had complained of chronic tension. Patients showed significant decreases in their muscle tension levels with successive biofeedback training sessions. No significant differences were found between the schizophrenic, neurotic, and tension headache groups. A further contribution was the finding that patients with diverse socioeconomic and educational levels benefited similarly from EMG biofeedback training.

Electromyographic (EMG) biofeedback of frontalis muscles has recently been reported as effective for nonpatient volunteers in treating problems of chronic tension and tension headaches (Budzynski, Stoyva, & Adler, 1970; Raskin, Johnson, & Rondestvedt, 1973). To date, no study has compared the effectiveness of EMG biofeedback on the frontalis muscles with different diagnostic groups of patients in a public psychiatric outpatient clinic. The present study was done to determine if outpatients diagnosed as schizophrenic, neurotic, or having tension headaches with serious and chronic tension would respond to EMG biofeedback.

The subjects were 14 outpatients whose clinical diagnoses were schizophrenia (6); neurosis (5); and tension headache (3). Ten of the patients were women with a mean age of 38 years; 4 were men with a mean age of 40 years. All subjects participated voluntarily in this study to learn tension reduction.

This study was presented at the annual meeting of the Western Psychological Association, Seattle, Washington, April 23, 1977.

Appreciation is extended to Lupe Guzman for her help in collecting the data.

Requests for reprints and for an extended report of this study should be sent to Frank X. Acosta, Department of Psychiatry and the Behavioral Sciences, University of Southern California School of Medicine, 1934 Hospital Place, Los Angeles, California 90033.

EMG levels were recorded in microvolts (range = 2-150 μ v) by a Model BTF-401 Biofeedback Technology, Inc., instrument. Three silver/silver chloride electrodes were placed across the forehead, approximately 1 inch (3.54 cm) above the eyebrows. A modulated tone via a table-mounted speaker provided auditory feedback to the patient. The pitch of the tone reflected the level of frontalis muscle tension.

Patients were seated in a reclining chair with eyes closed. Patients were scheduled for 1 biofeedback session per week and had to complete 10 or more sessions to be included in the study. The first visit by each patient to the biofeedback laboratory consisted of (a) taking baseline EMG measures; (b) the collection of demographic data; (c) administration of a brief IQ test, the Kent Intelligence Scale; and (d) viewing of a slide-tape cassette. Using cartoon characters and photographs, the slide tape explained the concept of biofeedback, its purpose, and how the equipment worked. Fifteen minutes of EMG baseline were recorded, which consisted of simply recording frontalis muscle EMG without any feedback being given; values were generated at 30-sec intervals. The technician recorded the values and plotted them on semilog graph paper. At the end of the baseline session and on all subsequent sessions, the subject was shown the plot of his/her EMG values and was told whether it indicated high, moderate, or low muscle tension.

The second visit by each subject was the first biofeedback training session. Each session consisted of 10 minutes of prebiofeedback EMG

baseline, during which no biofeedback tone was heard; followed by 15 minutes of biofeedback, during which the subject was instructed to reduce his/her tension by reducing the pitch of the tone from the speaker; and then 5 minutes of postbiofeedback baseline, again with no tone. Subjects were instructed to try and relax with their eyes closed but were not to fall asleep.

For data analysis, each biofeedback session was divided into four within-session measures: prebiofeedback baseline (10 minutes), first half of the biofeedback (7½ minutes), second half of the biofeedback (7½ minutes), and postbiofeedback baseline (5 minutes). Mean EMG values for each of the four measures were recorded for each biofeedback session. Several sessions were averaged to form three session blocks to even out some of the session-to-session within-subject variation. Block 1 consisted of Session 1 modified by averaging 15 minutes of no-feedback baseline of the subject's first visit with the 10 minutes of prefeedback baseline of Session 1. This gave a total of 25 minutes of prefeedback baseline covering two different visits. Block 2 consisted of averaging Sessions 4, 5, and 6. Block 3 consisted of averaging Sessions 8, 9, and 10. The study consisted of a $3 \times 3 \times 4$ factorial design, with 3 levels of diagnosis, 3 levels of session block, and 4 levels of within-session measures.

The results of a three-way analysis of variance with repeated measures showed a significant decrease ($p < .05$) in EMG levels across the three session blocks. Duncan's multiple-range test indicated that Blocks 2 and 3 both differed significantly from Block 1 ($p < .05$). This indicated that the three patient groups did lower their EMG levels with successive biofeedback training sessions. Although the schizophrenic ($M = 18.0$), neurotic ($M = 16.1$), and tension headache ($M = 29.8$) groups had different overall mean EMG levels, the analysis of variance showed no significant differences between the three diagnostic groups. No significant differences were noted for the within-session measures nor for any interactions.

To see if factors other than diagnosis may have affected the biofeedback learning, subjects

were grouped according to the following factors: intelligence, education, social class, motivation, source of referral to the study, and final disposition of the patient. Analyses of variance were performed on subject EMG levels for these factors, and no significant effects were found. However, the analyses of EMG values across Session Blocks 1, 2, and 3 were consistently significant (varying from $p < .01$ to $p < .10$). This persistent decline in EMG values across the 10 sessions further supports the findings that the patients did, in fact, lower their frontalis muscle tension with successive biofeedback training sessions.

The findings on IQ and education are of particular importance when compared with Townsend, House, and Addario's (1975) biofeedback study in a clinical setting, which screened out subjects who fell in the low IQ ranges or had less than an eighth-grade education. In contrast, our study suggests that learning to reduce tension through EMG biofeedback is applicable to individuals with diverse backgrounds.

Unlike other biofeedback studies that usually report findings based on 2-5 sessions per week (Budzynski et al., 1970; Raskin et al., 1973; Townsend et al., 1975), the patients in our study typically had only one biofeedback session per week. Interestingly, this less frequent rate of biofeedback proved to be sufficient to produce a significant reduction in frontalis muscle tension.

Cumulative Subject and Author Indexes to Psychological Abstracts 1975-1977

*Summarizing over 77,000 articles in
three handsome, permanent volumes*

Published by The American Psychological Association

The three volumes of this vital reference tool include cumulative indexes by subject and author of all the material included in 36 issues of *Psychological Abstracts* . . . a total of over 77,000 articles. Covering the three-year period from January 1975 through December 1977, the index includes not only the material previously published in the six semi-annual indexes but also additional bibliographic data making it easier to find both original sources and abstracted material.

These permanent volumes, created to withstand years of active use, are approximately 10" x 14", printed on durable, acid-free paper and handsomely encased in Class A Library bindings.

With one volume referencing material by author name and two by subject matter, the cumulative indexes will facilitate research for PA subscribers and students, researchers and others interested in psychological literature.

Evaluation of Psychological Service Delivery Programs

Special Issue of Professional Psychology

Evaluation of Psychological Service Delivery Programs is the title of a special November, 1977 issue of Professional Psychology. Editor Allan Barclay and guest Co-editors Bob and Evelyn Perloff have assembled a distinguished collection of articles that brings readers up to date on the evaluation of psychological services. The issue addresses the need to justify the effectiveness of service delivery programs not only in terms of cost but more importantly in terms of human benefits.

Sample Topics and Contributors

A sample of the topics and contributors appearing in this issue includes: Theodore Blau on quality of life; Nicholas Cummings on psychotherapy; Howard Blane on alcoholism; S. B. Sells and associates on drug abuse; and NIMH's Bertram Brown, Benjamin Liptzin and James Stockdill on the federal view of mental health program evaluation.

Ordering Information

Single copies of the issue are available from the Order Department at APA for \$5 each. All orders \$25 or under must be prepaid. Please make checks payable to APA. Send your orders to:

Order Department, P.P.

For the First Time...

an easy reading, practical, step by step guide to

A must for

- Full and Part-time private practitioners.
- Those who have ever even considered entering private practice.

**"Reduces the chance of
failure or disappointment."**

An entertaining, well organized book complete with worksheets, plans, and practical approaches to the everyday "nuts and bolts" business aspects of private practice.

MARK H. LEWIN, an ABPP Diplomate, distinguished author and editor, and founder of a thriving independent psychological service center, gives step-by-step procedures for:

- Assessing your readiness for private practice
- Preplanning the practice
- Setting up the office
- Developing new referrals
- Managing your time
- Effective use of lawyers and accountants
- Evaluating the practice as it develops
- Budgeting, fee setting, controlling costs and tax expenses

TAKE TIME

As an APA member,
your time is worth up to \$100 a day.

Hospital Indemnity

pays you \$40, \$60, \$80 or \$100 a day — every day that you are hospitalized. Double the amount when you are in an Intensive Care Unit.

A full year of benefits — with no waiting period. Your family can be covered too.

Your time in the hospital is worth money.
Money you can use any way you want.

Because your time is worth money.

Take time and mail this coupon today.

Could you use objectively obtained estimates of strengths and interrelationships of the id, ego, and superego in your diagnostic work? In your research on personality? Are you just plain curious about how these basic concepts of psychoanalytic theory might be quantified?

The I E S TEST

utilizes four independent subtests to measure important aspects of id, ego, and superego functioning. Materials are easy to handle. Tasks are disarming and are intrinsically interesting to almost anyone. Evaluation takes as much time, thought, and sophistication as for any other test giving important basic information about the personality.

The *Journal of Consulting and Clinical Psychology* publishes original contributions on the following topics: (a) the development, validity, and use of techniques of diagnosis and treatment in disordered behavior; (b) studies of populations of clinical interest, such as hospital, prison, rehabilitation, geriatric, and similar samples; (c) cross-cultural and demographic studies of interest for the behavior disorders; (d) studies of personality and of its assessment and development where these have a clear bearing on problems of consulting and clinical psychology; or (e) case studies pertinent to the preceding topics. In order to improve the use of journal resources it has been agreed by the two Editors concerned that the *Journal of Consulting and Clinical Psychology* will no longer consider manuscripts dealing with the etiology or descriptive pathology of abnormal behavior, and the *Journal of Abnormal Psychology* will no longer consider articles dealing with the diagnosis or treatment of abnormal behavior. Articles that appear to have a significant contribution to both of these broad areas may be sent to either journal for editorial decision. Papers of a theoretical nature will also be considered within the space limitations of the journal.

Manuscripts: Submit manuscripts in triplicate to the Editor-elect, Sol L. Garfield, Department of Psychology, Washington University, St. Louis, Missouri 63130 according to instructions provided elsewhere in the journal. Authors submitting a manuscript previously considered for publication in another APA journal are invited to inform the Editor, who will then seek to obtain independent reviews, thus avoiding the possibility of repeated reviewing by the same consultant.

Copyright and Permission: All rights reserved. Written permission must be obtained from the American Psychological Association for copying or reprinting text of more than 500 words, tables, or figures. Permissions are normally granted contingent upon like permission of the author, in addition to the APA copyright notice on the first page of reproduced material, and payment of a fee of \$10 per page, table, or figure of APA material. Permission and fees are waived for authors who wish to reproduce their own material for personal use. Fees only are waived for authors who wish to use their own material commercially. Abstracting is permitted with credit to the source. Libraries are permitted to photocopy beyond the limits of U.S. copyright law: (1) those post-1977 articles that carry a code at the bottom of the first page, provided the per-copy fee indicated in the code is paid through the Copyright Clearance Center, P.O. Box 765, Schenectady, NY 12301; (2) pre-1978 articles without fee. Instructors and educational institutions are permitted to photocopy isolated articles for noncommercial classroom or library reserve use without fee. Address requests for permission to the Permissions Office, APA, 1200 Seventeenth Street, N.W., Washington, D.C. 20036.

Subscriptions: Subscriptions are available on a calendar year basis only (January through December). Nonmember rates for 1978: \$32 domestic, \$34 foreign, \$6 single issue. APA member rate: \$16. Write to Subscription Section, APA.

Reprints: Authors may order reprints of their articles from the printer when they receive proofs.

Back Issues and Back Volumes: For information regarding back issues or back volumes write to Order Department, APA.

Microform Editions: For information regarding microform editions write to any of the following: Johnson Associates, Inc., P.O. Box 1017, Greenwich, Connecticut 06830; University Microfilms, Ann Arbor, Michigan 48106; or Princeton Microfilms, Princeton, New Jersey 08540.

Change of Address: Send change of address notice and a recent mailing label to the attention of the Subscription Section, APA, 30 days prior to the actual change of address. APA will not replace undelivered copies resulting from address changes; journals will be forwarded only if subscribers notify the local post office in writing that they will guarantee second-class forwarding postage.

Published bimonthly (beginning in February) in one volume per year by the American Psychological Association, Inc., 1200 Seventeenth Street, N.W., Washington, D.C. 20036. Printed in the U.S.A. Second-class postage paid at Washington, D.C., and at additional mailing offices.

Effects of Dopamine Synthesis Inhibition on WAIS Comprehension

Edward F. Donnelly, Henry A. Nasrallah, Richard Jed Wyatt,
J. Christian Gillin, and Llewellyn B. Bigelow

National Institute of Mental Health, St. Elizabeths Hospital, Washington, D.C.

A previous study has shown that parkinsonian patients treated with L-dopa had decreased scores over time on the Comprehension subtest of the Wechsler Adult Intelligence Scale (WAIS), whereas scores on all other 10 subtests of the WAIS increased. It was hypothesized that if L-dopa treatment, which increases dopamine activity in the brain, is directly related to an apparent deleterious effect on the WAIS Comprehension, then a drug such as alpha-methyl-*para*-tyrosine (AMPT), which decreases dopamine activity, might have an augmenting effect on this subtest. A therapeutic trial of AMPT in a group of chronic schizophrenic patients provided an opportunity to test this hypothesis. It was found that Comprehension scores improved significantly with AMPT. Other clinical rating instruments failed to show any changes. The implications of using a psychometric instrument to assess specific, but clinically obscured, drug effects on intellectual functioning are discussed.

Over the past 25 years, treatment of the schizophrenic disorders has been dramatically altered with the widespread use of antipsychotic drugs. A large number of studies have established that chlorpromazine and other antipsychotic drugs are effective for the treatment of acute psychotic decompensation and the prevention of relapses (Engelhardt, Freedman, Rosen, Mann, & Margolis, 1964; Lasky, Klett, Caffey, Bennett, Rosenblum, & Hollister, 1962; National Institute of Mental Health, 1964).

Frequent side effects of the treatment of schizophrenic patients with antipsychotic drugs are tremors, muscle rigidity, stiff posture, shuffling gait, and drooling. Because of the similarity of these side effects to the symptoms of Parkinson's disease, they have been referred to as "parkinsonian" side effects. Further, it has been shown that these side effects in schizophrenic patients are related to the blockade of dopamine receptors

by antipsychotic drugs (Snyder, Banerjee, Yamamura, & Greenberg, 1974). Research in parkinsonism itself has revealed that some brain areas contributing to the control of body movements have lower concentrations of the neurotransmitter dopamine than normals. When parkinsonian patients were treated with L-dopa (dopamine itself cannot be used in replacement therapy because it does not cross between the blood stream and brain tissue, whereas its synthetic precursor, L-dopa, does), their symptoms often disappeared or became less severe.

Improvement of schizophrenic symptoms seems to be associated with drugs that decrease brain dopamine activity, whereas improvement in parkinsonian symptoms is associated with drugs that increase dopamine activity in the brain.

It is generally agreed that the Comprehension subtest of the Wechsler Adult Intelligence Scale (WAIS) is a measure of some form of "judgment." A recent study (Donnelly & Chase, 1973) of parkinsonian patients placed on therapeutic trials of L-dopa reported a decrease in the Comprehension scores after several months of treatment; in con-

Requests for reprints should be sent to Edward F. Donnelly, National Institute of Mental Health, St. Elizabeths Hospital, William A. White Building, Washington, D.C. 20032.

In the public domain.

trast, scores on all other 10 subtests of the WAIS showed an increase. A possible drug-induced defect in this type of judgment is consistent with exacerbation of psychosis in chronic schizophrenic patients after L-dopa treatment (Yaryura-Tobias, Wolpert, Dana, & Merlis, 1970) and with other reports of agitation, confusion, paranoia, delusions, and depression in parkinsonian patients after L-dopa treatment (Cotzias, Papavasiliou, & Gellene, 1969; Yahr, Duvoisin, Shear, Barrett, & Hoehn, 1969; Barbeau, 1972). These findings, suggesting that L-dopa is detrimental to cognitive functioning, led us to hypothesize that depleting the brain of its dopamine stores might be accompanied by an increase in the scores of the Comprehension subtest. Alpha-methyl-*para*-tyrosine (AMPT), a drug known to inhibit the rate-limiting enzymatic step in dopamine synthesis (Spector, Sjoerdma, & Udenfriend, 1965), was used to test our hypothesis.

The main objective of the present study, a part of a more extensive study of the potential clinical effectiveness of AMPT in schizophrenia (Nasrallah et al., 1977), was to determine if the WAIS Comprehension scores of a small but relatively homogeneous group of chronic schizophrenic patients, already receiving high doses of antipsychotic drugs (e.g., chlorpromazine, fluphenazine, and thioridazine), would increase with the administration of AMPT.

Method

Subjects

Nine voluntary male chronic schizophrenic patients, selected for their poor response to conventional antipsychotic drugs, who were hospitalized on a research ward at St. Elizabeths Hospital, Washington, D.C., participated in the present study. They ranged in age from 19 to 35 years, with a mean of 26.2 years. Length of hospitalization ranged from 2 to 15 years, with a mean of 8.3 years. Each patient satisfied the research diagnostic criteria (Spitzer, Endicott, & Robins, 1975) for chronic undifferentiated schizophrenia.

Procedure

The patients had been on the research ward for 4 to 13 months when consent was obtained from them and their families to participate in this study. Although the patients were not on optimal dosages

of medication at the time of the study, experience indicated that greater doses of antipsychotic drugs would not have enabled them to leave the hospital for a sustained period of time. Each of the patients had been stabilized on a constant dose of antipsychotic drugs (average equivalent dose of chlorpromazine = 800 mg/24 hr) for several months before the study, and all were kept on the same dose throughout the study. Patients entered the protocol over a 12-month period as they became available.

AMPT and placebo were administered in a double-blind nonrandom design, with periods on drug and placebo for each patient. A 4-week period of placebo administration preceded and followed a 3-week trial of AMPT. A fixed number of capsules (a total of 12 placebo, placebo plus AMPT, or AMPT capsules alone) was given daily to each patient in four divided doses. To assess each patient's clinical status, the Comprehension subtest of the WAIS was administered and scored by the same psychologist at the end of the first placebo period, the AMPT, and the last placebo period. Two other psychologists, blind to the design of the study, also scored this subtest (intrater reliability $W = .939$).

The patient's clinical status was also monitored daily by the National Institute of Mental Health (NIMH) Inpatient Behavioral Rating Scale, a 26-item nurses' rating scale characterizing a broad range of psychopathology and showing good interrater reliability (Green, Bigelow, O'Brien, Stahl, & Wyatt, 1977). Nurses completing this form were blind to the experimental design and medication status of the patients. The Brief Psychiatric Rating Scale (BPRS; Overall & Gorham, 1962) was completed by a psychiatrist who also was blind to design and medication status.

Results

WAIS Comprehension Subtest Scores

A Friedman two-way analysis of variance indicated significant differences ($\chi^2 = 11.56$, $p < .001$) between the AMPT trial and the two placebo periods. The Wilcoxon matched-pairs signed-ranks test was then used to determine the differences between the AMPT trial and the two placebo periods. Means and standard deviations from the first placebo period to the AMPT trial were 6.56 ± 2.54 , and 10.33 ± 2.16 , respectively ($T = 1$, $p < .01$). Means and standard deviations from the AMPT trial and the second placebo period were 10.33 ± 2.16 and 8.00 ± 2.26 , respectively ($T = 0$, $p < .01$). However, there was no significant difference between the first and second placebo periods ($T = 10$). Inspection of the individual scores of the nine patients in Table 1 shows that every patient got worse

during the second placebo period, and all but one improved during the AMPT trial.

Other Patient Ratings

The means of the psychosis scores of the nurses' NIMH Inpatient Behavioral Rating Scale did not show significant changes among the first placebo, AMPT, and second placebo periods (11.42 ± 3.11 , 11.93 ± 2.54 , and 11.23 ± 3.96 , respectively). Similarly, the BPRS schizophrenia scores did not show significant changes among the first placebo, AMPT, and second placebo periods (9.54 ± 3.39 , 7.56 ± 3.11 , and 8.43 ± 3.11 , respectively).

Discussion

The findings of this study support the hypothesis that depleting the brain of its dopamine stores produces an increase in WAIS Comprehension scores. Thus, judgment, as measured by the Comprehension subtest, in schizophrenic patients appears to improve in a relatively "hypodopaminergic" state. Moreover, our results also suggest that Comprehension may be a more sensitive measure of subtle drug-induced intellectual changes in schizophrenic patients than the nurses' rating scale (NIMH Inpatient Behavioral Rating Scale) or the interview-based BPRS.

The possibility of artifacts arising consequent to repeated testing in each patient at relatively short intervals must be considered. It is conceivable that the increase in scores at the time of the second testing (AMPT trial) was a function of a practice effect. Likewise, the decrement in scores observed at the third testing (second placebo trial) could be attributed to a boredom effect. Such a coincidence of influences, however, seems unlikely.

The possibility that improvement in the Comprehension scores was due to a placebo effect also must be considered. If it is due to such an effect, it would have to be operative only between the 4th and 7th week of the protocol and be sufficiently evanescent to disappear at the time of the third testing, given at the close of the 11th week of the study.

Results could not be due to a group trend or overall shifts in the ward environment, be-

Table 1
Individual Comprehension Scores (Raw) of Nine Chronic Schizophrenic Patients on AMPT and Two Placebo Periods

Patient	First placebo	AMPT	Second placebo
1	0	7	6
2	6	11	10
3	8	7	4
4	9	13	11
5	6	9	7
6	8	11	9
7	6	10	7
8	8	12	7
9	8	13	11

Note. AMPT = alpha-methyl-*para*-tyrosine.

cause the patients were run at different times, not as a cohort.

To assess whether administration of AMPT affected central dopamine in this study, we measured plasma prolactin levels. The release of this hormone, secreted by the pituitary gland, is normally inhibited by dopamine. Since serum prolactin levels did increase significantly during this study, it appears likely that AMPT did inhibit synthesis of dopamine in the brain (Nasrallah, Rogol, Wyatt, & Gillin, Note 1).

These results, together with the earlier finding that parkinsonian patients performed worse on the Comprehension subtest when treated with L-dopa than without, suggest that performance on this subtest is inversely related to central dopaminergic activity.

At the present time, assessment of drug-induced changes in psychiatric populations relies heavily on rating scales, symptom checklists, and self-reports. Our data, however, suggest that the relationship between a specific intellectual function and the specific brain neurotransmitter dopamine can be most accurately determined by quantitative assessment, that is, the patient's scored responses to the Comprehension subtest. Several studies that have investigated the effects of antipsychotic drugs on the WAIS scores of normal and schizophrenic subjects reported significantly improved scores (Abrams, 1958; Gardner, Hawkins, Judah, & Murphree, 1955; Gilgash, 1957), whereas others reported no changes (Judson & Mac Casland, 1960; Pare-

des, Baumgold, Pugh, & Ragland, 1966). One study (Gilgash, 1957) indicated that a group of schizophrenic patients showed a greater point average increase on the Comprehension subtest than on any other subtest of the Verbal scale subsequent to chlorpromazine medication. Since most of these studies were reported in the late 1950s and similar assessment by the WAIS has been rarely reported in the past decade, it seems that psychometric evaluation has been a neglected resource as a clinical dependent variable in determining the impact of drug treatment on intellectual functioning.

The manner in which the Comprehension subtest and AMPT covaried in the design of the present study suggests that this subtest, or possibly other subtests of the WAIS, in contradistinction to conventional behavioral rating scales, offers some promise for understanding the complexity of interacting variables in cognitive psychopharmacology. Further studies of drug-induced intellectual changes in schizophrenic patients should be directed at determining whether any of the other subtests of the WAIS are as sensitive as Comprehension in assessing changes and whether Comprehension is sensitive to the effects of drugs other than AMPT and L-dopa in designs similar to the present study.

Psychophysiological Effects of Progressive Relaxation in Anxiety Neurotic Patients and of Progressive Relaxation and Alpha Feedback in Nonpatients

Paul M. Lehrer

Department of Psychiatry
College of Medicine and Dentistry of New Jersey
Rutgers Medical School

Ten anxiety neurotic patients were given four sessions of individual instruction in progressive relaxation, and 10 patients served as waiting list controls. Ten nonpatients were assigned to each of the same conditions, and an additional 10 nonpatients were given four sessions of alpha feedback. Nonpatients showed more psychophysiological habituation over sessions than patients in response to hearing five very loud tones and to a reaction time task. Patients, however, showed greater physiological response to relaxation than did nonpatients. After relaxation, the autonomic responses of the patients resembled those of the nonpatients. The effects of relaxation were more pronounced in measures of physiological reactivity than in measures of physiological activity. Defensive reflexes yielded to orienting reflexes more readily in nonpatients than in patients. There was also a tendency for progressive relaxation to generalize to autonomic functions more than alpha feedback.

Progressive relaxation is one of the most venerable techniques of behavior therapy and one of the most investigated. Jacobson (1938) reviewed a number of the early case studies showing that progressive relaxation training produces extraordinarily low levels of muscle tension, and that patients suffering from a variety of psychological and psychosomatic disorders experience significant relief when they practice the technique. Gellhorn (1958) hypothesized that progressive relaxation reduces physiological reactivity through reduction in proprioceptive feedback from the muscles to the reticular system. However,

Davison (1966) disputed this "peripheralist" theory and argued that relaxation works on a more central, cognitive level, since subjects can still be anxious when their muscles are rendered almost completely flaccid by curare. A number of controlled studies have been done on the treatment effectiveness of relaxation. Relaxation has been found to be effective in treating the symptoms of insomnia (Borkovec & Fowles, 1973; Borkovec, Kaloupek, & Slama, 1975; Lick & Heffler, 1977; Nicassio & Bootzin, 1974; Woolfolk, Carr-Kaffashan, McNulty, & Lehrer, 1976); hypertension (Deabler, Fidel, Dillenkoffer, & Elder, 1973; Shoemaker & Tasto, 1975); tension headaches (Cox, Freundlich, & Meyer, 1975); and chronic anxiety (Townsend, House, & Addario, 1975).

This research was supported by Biomedical Research Support Grant 27-1985 from Rutgers Medical School.

The author is indebted to Ric Belser and Linda Duberstein, who trained the subjects and scored the data; to Alan Jusko, who got the equipment to work; to John Carpenter for his statistical advice; and to Robert Edelberg for his advice and support in all phases of this study.

Requests for reprints should be sent to Paul Lehrer, Department of Psychiatry, Rutgers Medical School, Piscataway, New Jersey 08854.

The first controlled studies on the psychophysiological effects of relaxation were done on reflexes of the skeletal muscles. Miller (1926) tested the finger withdrawal reflex in subjects who had been trained in progressive relaxation for 6 months. The reflex was smaller in subjects who were instructed to

relax than in those who were instructed not to do so. A more sophisticated control was added by Freeman (1933), who instructed all subjects to relax but had some subjects sit in a seat that required them to maintain some muscle tension in order to remain comfortable. The finger withdrawal reflex was smaller in the relaxation group in this study also. More modern studies of skeletal muscle activity have indicated that progressive relaxation can reduce frontalis electromyogram (EMG) activity more than control conditions (Cox et al., 1975). One study found that tape-recorded instructions in progressive relaxation reduced frontalis EMG activity more than did autogenic training (Staples, Coursey, & Smith, Note 1).

Since progressive relaxation operates primarily on the skeletal muscles, it can be expected to have a greater effect on this system than on other physiological systems. Davidson and Schwartz (1976) have argued that all relaxation techniques are not alike and that they probably have different effects on different physiological systems, depending on the system at which they are most directly aimed. Nevertheless, a number of studies have shown that under certain conditions, autonomic measures are also affected by progressive relaxation training. For example Paul (1969b) found that brief live progressive relaxation training reduced heart rate and respiration rate more than a control condition, and it reduced heart rate more than hypnotic suggestions to relax.

However, results have not been consistent. In another study, Paul (1969a) found that although live progressive relaxation training reduced a combined measure of physiological reactivity to an anxiety-provoking scene, no individual physiological measure was significantly reduced. Lehrer (1972) found that although relaxation reduced heart rate toward the end of a period of electric shock, it had no measurable effect on skin potential or respiration rate. Other studies have found no differences in autonomic activity between progressive relaxation and ordinary rest (Paul & Trimble, 1970; Grossberg, Note 2) or suggestions to relax (Edelman, 1970). Even EMG measures have not always significantly differentiated progressive relaxation training from

control conditions (Haynes, Moseley, & McGowan, 1975; Lehrer, 1972; Paul & Trimble, 1970). A number of factors may account for the discrepant results. Among these are population differences, techniques for independently assessing level of anxiety, intensity of training, and conditions of testing.

Population Differences

The effects of relaxation appear to be clearer among persons with high basal anxiety levels. Thus Wilson and Wilson (1970), studying patients in a general medical hospital, found that brief relaxation instructions reduced heart rate as compared with a control group that listened to a talk on the history of baseball, but only in high anxious subjects, as determined by responses to the IPAT Anxiety Scale. Also, Brandt (1974), studying college students, found that taped progressive relaxation instructions reduced the size and frequency of electrodermal responses, heart rate, and EMG when measured during relaxation training, but when these measures were repeated for a rest period after the second (and last) training session, only heart rate was different between the groups, and only among high scorers on the Fear Survey Schedule. It should come as no surprise that the effects of relaxation are easier to measure among anxious rather than nonanxious persons, since nonanxious persons are presumably able to relax without special training. Lader and Wing (1966) reported that anxiety neurotics do not show habituation of the skin conductance to repeated presentations of a loud (100 dB, 1,000 Hz) aversive tone. They also reviewed a number of other studies showing that anxiety neurotics have higher levels of sympathetic activity, slower habituation of the electrodermal response to noxious stimuli, and higher levels of some indicators of physiological arousal.

Method of Assessment of Anxiety

Although the studies by Brandt (1974) and by Wilson and Wilson (1970) suggest that the IPAT anxiety inventory and the Fear

Survey Schedule hold promise as screening devices for relaxation studies, most of the commonly used paper-and-pencil tests of anxiety probably do not measure the kind of gross psychopathology that was studied by Lader and Wing (1966). For example, Edelman (1970) used the Spielberger State-Trait Anxiety Inventory (STAI) as a screening device and found that neither anxious nor non-anxious subjects manifested any significant autonomic changes after tape-recorded relaxation instruction. Other paper-and-pencil tests may have the same problem, especially the commonly used Taylor Manifest Anxiety Scale (TMAS). In some instances the TMAS has been found to be significantly related to physiological measures, such as eyeblink conditioning (Spence & Taylor, 1966), conditioning of finger withdrawal reflex (Sloane, Davidson, & Payne, 1965), the Palmar Sweat Index during a verbal conditioning task (Haywood & Spielberger, 1966), conditioned heart rate accelerations (Dube, 1966), and basal heart rate (Lehrer, 1969). However, most studies have found no relationship between the TMAS and autonomic measures (e.g., Beam, 1955; Bitterman & Holtzman, 1952; Bursten & Russ, 1965; Calvin, McGuigan, Tyrrell, & Soyars, 1956; Lewinsohn, 1956; McGuigan, Calvin, & Richardson, 1959; Sloane et al., 1965; Spelman, 1966).

A similar lack of significant relationships has also been found between various physiological measures and the Maudsley Neuroticism Scale (Spelman, 1966; Sloane et al., 1965), Welsh's A factor (Katkin, 1965), McReynold's Assimilation Scale (McReynolds, Acker, & Brackbill, 1966), and several tests of situational anxiety (Katkin, 1966; Rosenstein, 1960). A possible reason for the inadequacy of these paper-and-pencil tests as measures of anxiety is that these tests may measure other things besides anxiety, for example, the willingness of people to describe themselves negatively or to admit emotional weaknesses. Thus Kimble and Posnick (1967) reported a correlation of .73 between the TMAS and a scale having nothing to do with anxiety that contained items matched with the TMAS on emotional importance and social acceptability.

Intensity of Training

None of the studies using brief relaxation instructions produced the size of changes implied in Jacobson's work (1938), in which people receive training over a period of months. Perhaps the intensive training given by Jacobson and his more strict adherents has a more profound physiological effect than the brief training procedures that are conventionally used, especially those that are administered in a single session and/or are given by tape recording.

Conditions of Testing

In almost all of the above cited studies that found brief relaxation training to be effective in altering psychophysiology, subjects were tested either while they were receiving relaxation instruction or while the trainer was still in the room immediately after live instruction. These conditions are not analogous to the clinical situation in which the patient must apply the training at home and may have exaggerated the effects of the relaxation training. This is suggested by Paul and Trimble's (1970) findings that live relaxation training (with the therapist in the room during testing) produces a greater physiological effect than tape-recorded instructions, and by Brandt's (1974) findings that the physiological effects of brief tape-recorded relaxation instructions are quickly attenuated after a training session is over.

Alpha Feedback

Electroencephalogram (EEG) alpha control has recently become a topic of broad interest and wide application. Early investigators have remarked on how the presence of alpha appears to be inversely related to anxiety (Jasper, 1937), and some modern work on alpha feedback has found that among subjects who do learn to control their alpha production, the production of alpha is usually associated with subjective feelings of relaxation, letting go, and a lack of focused thought (Brown, 1970; Nowlis & Kamiya, 1970). More recently, however, Orne and Paskewitz (1974) reported a study showing that under the

threat of shock, subjects who are given occipital alpha feedback still show increases in subjective anxiety, frequency of skin conductance responses, and heart rate, despite the fact that their levels of occipital alpha production remain high. Thus, although high levels of alpha are, under some conditions, associated with diminished anxiety, the production of alpha appears to be at least partially a differentiable process from subjective anxiety and autonomic reactivity.

Present Study

This study compared the physiological effects of progressive relaxation, alpha feedback, and a no-treatment control condition. The responses of psychiatric patients who were clinically diagnosed as suffering from severe anxiety were compared with that of non-anxious volunteer subjects who were not psychiatric patients. Subjects received approximately the same intensity of training as is usually given to patients in behavior therapy, and the testing was done during a separate session by an experimenter who was not involved in training the subjects to relax.

Loud Tones

The testing situation included a series of loud tones similar to those used by Lader and Wing (1966), who had found that tranquilizing medication allowed anxiety neurotics' skin conductance responses to the tones to habituate at a rate equal to the rate in normal subjects.

Reaction Time Task

The question is frequently asked whether relaxation makes people somnolent and less reactive to the environment in general or whether, as suggested by Wilson and Wilson's (1970) data, it reduces the specific effects of anxiety and *enhances* the ability to pay attention to the environment and to solve problems. A test of reaction times was thus included to test whether relaxation facilitates this type of "alertness" response and whether, on a physiological level, it affects the orienting reflex (cf. Graham & Clifton, 1966).

Alpha Feedback

The present study also included an alpha feedback condition that used a training procedure similar to that described by Brown (1970). The clinical and experimental studies cited above suggest that progressive relaxation would, especially among the anxious patients, generalize to autonomic reactivity, whereas alpha feedback would not generalize as much. Because of the difficulty in finding a sufficient number of suitable anxious patients who would be willing to participate in the study, I decided to test the alpha condition only on nonpatient volunteers. Light was used as a feedback signal rather than the more conventional tone signal so as not to unintentionally habituate these subjects to the noxious tones used in the testing situation. Although light may depress occipital alpha, it has also been found that the presence of light in a room may increase the effects of alpha feedback training (Paskewitz & Orne, 1973).

Method

Subjects. The subjects for this experiment were 20 anxiety neurotic patients and 34 nonpatient volunteers. The patients were recruited through their therapists, who are professionals at the Rutgers Mental Health Center or members of the faculty of the Department of Psychiatry of Rutgers Medical School and/or of the Graduate School of Applied and Professional Psychology at Rutgers University. Patients were accepted whose symptoms were "primarily" those of anxiety (according to the report of their therapists), who were not psychotic, and who were not regularly taking any medication other than minor tranquilizers. Most of the anxious subjects were diagnosed as anxiety neurotic. Patients with histories of neurological or cardiovascular disorders were excluded, and testing sessions were held only after patients had not taken any medication for at least 24 hours. Ten patients each were included in the relaxation and control (ordinary rest) conditions. The nonpatients were recruited from newspaper advertisements, notices to staff members at Rutgers Mental Health Center, and signs on bulletin boards. Subjects were accepted for the experiment only if they reported that they were in excellent physical and emotional health, were not taking any psychoactive medication, and were not currently receiving any form of treatment for an emotional problem. Subjects were assigned to groups on as random a basis as possible, given difficulties in scheduling. Eleven subjects were assigned to the relaxation group, 11 to the alpha feedback group, and 12 to the con-

Table 1
Design of the Experiment

Condition	Population	Pretest	Training
Relaxation	Patients and nonpatients	5-min rest; 5 tones, 100 dB, 1,000 Hz	4-5 sessions of training in progressive relaxation during a 3-week period
Control	Patients and nonpatients	5 reaction time trials with variable interval foreperiods	3-week wait for training
Alpha feedback	Nonpatients	3-min rest	4-5 sessions of alpha feedback during a 3-week period

Note. Posttest consisted of the same procedures as the pretest.

trol group (ordinary rest). Both patients and nonpatients in the control group were offered relaxation training after their participation in the two testing sessions. They were not told that they were members of a control group. The complete design is summarized in Table 1.

Testing procedure. Testing sessions were held approximately 3 weeks apart. Subjects in the relaxation and alpha feedback groups received their training between testing sessions, whereas subjects in the control group were tested at the same intervals but were not in contact with the project between testing sessions.

In each testing session, subjects were first wired to the equipment, and, in both conditions, before and after training, they were asked to close their eyes and to relax as deeply as possible in the reclining chair. They were told to expect to hear some loud tones after several minutes but to try to remain relaxed through them.

After approximately 5 min of resting, five aversive tones were presented for a duration of 1 sec each with an interstimulus interval varying between 30 and 60 sec. They were presented from a speaker at a located several feet behind the subject's chair, at a frequency of 1,000 Hz and an intensity of 100 dB(A).

Approximately 30 sec after the last aversive tone, the experimenter reentered the subject room, put a pushbutton switch in the subject's nondominant hand, and told the subject that the next task consisted of a series of reaction time trials. Subjects were told to expect to hear "softer, deeper" tones than they had heard before and that they would not be aversive. Each tone was a "get ready" stimulus. Subjects were told to press the button as quickly as possible after the tone went off. The tones were presented at 60 dB and approximately 300 Hz for durations varying between 5 and 15 sec, with interstimulus intervals of between 30 and 60 sec. Following the last trial, subjects were given an additional 3-min rest.

Subjects were also administered the State Anxiety scale of the STAI before and after each session. Before each session they were asked to fill it out

with reference to how they felt "right now." After the session they were asked to fill it out as to how they felt "during the session." All subjects were also administered the STAI Trait scale prior to their first session.

Apparatus. Physiological measures for the first 10 subjects tested, approximately equally distributed among groups, were taken on a Grass Model 5 polygraph. The rest of the subjects were tested on a Beckman Type R Dynograph. The following measures were taken: skin conductance, heart rate, and EEG from the dominant occipital area.

Skin conductance was measured from a pair of silver-silver chloride electrodes, 1 cm² each, mounted, in a special holder to facilitate recording from the palmar surface of a finger (Edelberg, Note 3). The middle finger of the dominant hand was used. K-Y jelly was used as the electrolyte. Resistance was measured in kilohms on the Grass polygraph, which was later converted to micromhos conductance for data analysis. On the Beckman polygraph, a Lykken coupler was used for direct measurement of skin conductance. Heart rate was measured through a cardi tachometer from standard electrocardiogram electrodes attached to the right arm and left leg. EEG leads were attached to the dominant occipital area (O₁ or O₂) and to both earlobes as the reference point. A ground lead was attached to the forehead. Alpha was filtered by an instrument, similar to that described by Paskewitz (1971), which provides a voltage output when a criterion amplitude of filtered alpha is present. For the testing sessions, the criterion level for alpha for all was set at 19 μ V.

Relaxation training. Subjects in the progressive relaxation group were administered four sessions of individual training using an abbreviated form of Jacobson's (1938, 1964) technique. Subjects were asked, alternately, to tense and to relax each of 35 muscle groups. Subjects were instructed to tense each muscle as little as necessary to barely feel the proprioceptive sensations of muscle contraction. Each muscle group was worked with repeatedly until the subject could feel the muscle contraction without engaging in any overt movement. Each subject was

trained at his or her own pace. In most subjects the arms and some of the leg muscles were trained during the first session, the remainder of the leg muscles and the trunk were trained during the second session, and the facial muscles were trained during the third session. The fourth session was generally devoted to review and general relaxation. Subjects were asked to rate their relaxation during each session from 0, "as relaxed as I ever felt," to 100, "very anxious." If a subject's self-rating of relaxation did not fall below 10 by the fourth session, an additional session of training was given. Subjects were told to practice the technique at home for 1 hour daily, but they were given no written or taped material to take home with them.

Alpha feedback. Dominant occipital alpha feedback was given in four sessions of individual training. The occipital area was chosen for feedback because of the high density of alpha often recorded from that site and because of previous reports of success in conditioning alpha from that region, including one study showing that increased alpha can persist during aversive stimulation (Chisholm, De Good, & Hartz, 1977). Dominance was assessed simply by asking subjects whether they are right-handed or left-handed. In each session the subjects were first wired to the equipment and were then asked to lie back on a reclining chair, to close their eyes, and to try to keep their minds blank. This, they were told, is the best way to stay in an "alpha state." Through their closed eyelids, they were told, they would see a light flashing on and off. The presence of this light indicated that the subject was emitting alpha. A small flashlight bulb was mounted on the 8-foot (2.4 m) ceiling directly above the subject's head, and it flashed on when the subject's alpha amplitude reached a specified criterion. Generally this criterion was 19 μ V. If the subject emitted less than approximately 30% alpha, the criterion was lowered and the response was shaped. Subjects were given approximately 40 minutes of training during each session. They were told to try to put themselves into an alpha state at home in daily 1-hour practice sessions, without feedback. As in the relaxation group, alpha feedback subjects were asked to rate their level of relaxation after each session and were given a fifth session of training if they did not rate themselves below 10 after the fourth session.

Results

Most analyses reported below are on difference scores between values on the pretest session and values on the posttest session. Each data point in the first session was subtracted from the corresponding point in the second session (posttest). Thus, in the analyses of variance that were computed, the *F* and *p* values for each main effect or interaction are identical to the interaction between that effect and an implicit sessions factor

from an analysis done on the raw session scores (vs. the session-difference scores used here). Covariance adjustments were also used in these analyses to adjust for some differences between experimental groups in the first session that were determined by analyses of variance done on the pretest session alone. The session-difference scores were adjusted for pretest (Session 1) levels of the same measure. Also, to test the significance of habituation across sessions and across trials, analyses of variance were computed on the raw scores for all data points within each of the sessions, and analyses of variance were computed with an additional between-groups measure for session. All analyses include a between-groups factor (treatment) and a within-group factor (time). The time factor consists of five trials each for the loud tones and reaction time task and eight epochs or time samples of 15 sec each for the two rest periods at the beginning and end of each session (i.e., before the first loud tone and after the last reaction time trial). Data were scored for 15 sec before and after each loud tone and for the duration of each get ready stimulus and an equivalent time period before each reaction time trial.

Wherever data points were missing due to equipment difficulties, they were filled in using the unweighted means solution. Data were analyzed on an IBM 370 computer using the Data-Text program (Armor & Couch, 1972) Versions 3.0 and 3.1. Each measure was first tested for skewness, kurtosis, and heteroscedasticity. Where necessary, normalizing transformations were used, and, in all cases, the assumptions of the analysis of variance and covariance were met.

Combined analyses of patients and nonpatients in the relaxation and control conditions. To compare diagnostic groups and treatment effects in a single analysis, the alpha feedback condition, which was only given to nonpatients, was excluded in some analyses. In these analyses the covariance - adjusted session-difference scores have two between-groups measures, diagnosis (patient vs. nonpatients) and treatment (relaxation vs. control), and one repeated measure, time.

Separate analyses of patients and nonpatients. To test the significance of treatment

During RT trials	2.5	1.9	2.0	1.9	2.1	1.6	2.5	1.7	2.1	2.3

Note. RT = reaction time.

^a A negative cardiac deceleration reflects a lower minimum heart rate before the stimulus than after the stimulus. A negative cardiac acceleration reflects a higher maximum heart rate before the stimulus than after the stimulus.

and habituation effects in each of the two populations that were studied, the data from each population were submitted separately to the analyses of variance described above, without the between-groups factor of diagnosis.

Subjective Anxiety

Trait Anxiety

As a check on our diagnostic procedures and to check on the randomness of assignment to treatment conditions, a two-factor analysis of variance was done on the STAI Trait Anxiety scale scores, with diagnosis and treatment as between-groups measures. As expected, patients scored significantly ($p < .005$) higher than nonpatients. The treatment effect was not significant, indicating that on this measure, the assignment of subjects to groups was effectively random.

State Anxiety

The STAI State Anxiety scale was analyzed by an analysis of variance with two between-

groups measures (diagnosis and treatment) and two repeated measures (time and session). The two levels of the time factor were pre-session and during session. The Diagnosis \times Time interaction was significant at $p < .004$, indicating that the patients reported themselves to be more anxious than the nonpatients at the beginning of each session. The analysis of variance on Session 1 scores yielded a significant ($p < .02$) effect for treatment, indicating that on this measure, the method of random selection to groups was not adequate and that the subjects assigned to the control group admitted less anxiety than the subjects assigned to the treatment groups (Table 2). Thus an analysis of variance was done on the covariance-adjusted difference scores, as described above. Reported anxiety decreased significantly more in the relaxation group than in the control groups. Separate analyses of the patient and non-patient groups revealed that patients and nonpatients both habituated over sessions but

Figure 1. Differences between the pretest and the posttest, adjusted for the level for each score during the pretest session.

Note. RT = reaction time.

^a Unless otherwise specified, this refers to the treatment effect on the covariance-adjusted session-difference scores.

^b This column refers to an analysis of both the patients and the nonpatients, for the relaxation and control conditions only.

^c Patients emitted higher skin conductance responses (SCRs) to the first tone than nonpatients and rated themselves as more anxious than nonpatients at the beginning of each session. The Diagnosis \times Time interactions are, respectively, significant at $p < .03$ and $p < .001$.

^d Increases in alpha are scored as habituation.

^e These values are for the Treatment \times Diagnosis effect on the covariance-adjusted session-difference scores. The overall Treatment effect is not significant.

^f Here an increase in cardiac deceleration is rated as habituation.

^g The Session \times Trial effect is also significant at $p < .05$, indicating that habituation over trials is faster in the posttest than in the pretest.

^h Patients also emitted significantly smaller skin conductance responses than nonpatients.

* $p < .10$.

** $p < .05$.

*** $p < .01$.

**** $p < .005$.

that the covariance-adjusted treatment effects were significant only for the nonpatients. A trend analysis on the session-difference scores, with the nonpatient relaxation group assigned a value of 1, the alpha feedback group a value of 2, and the nonpatient control group a value of 3, revealed a linear trend of borderline significance ($p < .052$), suggesting that relaxation was most effective in reducing anxiety, the alpha feedback condition second, and the control condition least (Figure 1).

EEG Alpha

Percent alpha

Percent alpha of 19 μ V or greater was scored for each of the time periods described above. As can be seen in Figure 1, relaxation appears to have increased patients' tendencies to emit alpha waves. However, paradoxically, percent alpha appears to have *decreased* over time in the nonpatient relaxation group relative to the nonpatient alpha and control groups. The Diagnosis \times Treatment effect was significant for most time periods (Table 3) in the combined analysis. Analyses of the pretest session scores revealed significant differences between treatment groups ($p < .02$) for the epochs following the loud tones, with

the alpha feedback group having less alpha than the other two groups (Table 2). Covariance-adjusted analyses of variance on the pretest versus posttest change scores revealed that among the patients, differences between treatments were significant for the epochs following the loud tones and were of borderline significance for the epochs preceding the loud tones and reaction time trials. For the nonpatients, none of the differences were significant. A trend analysis was computed for the nonpatients across groups on the session-difference scores, with the relaxation group assigned a value of 1, the alpha feedback group a value of 2, and the control group a value of 3. A significant ($p < .05$) quadratic trend was found for the beginning-of-session rest, before and after the loud tones, and before the reaction time trials, thus indicating that the alpha feedback condition produces greater increases in percent alpha than the other two groups of nonpatients.

Alpha Blocking

Alpha blocking was assessed by subtracting the prestimulus percent alpha from the post-stimulus value for each trial of the loud tones and the reaction time "ready" stimuli. There were no differences on this measure as a func-

Table 4

Differences Between Patients and Nonpatients in Heart Rate

Measure	<i>M</i>		<i>F</i>	<i>p</i>
	Patients	Nonpatients		
HR at stimulus onset				
Tones	77.7	71.2	2.50 ^a	.12
RT trials	76.4	70.4	2.10 ^a	.16
Minimum HRs				
Pretone	72.3	64.6	3.71 ^a	.06
Posttone	72.4	64.0	4.52 ^a	.04
Pre-RT trials	72.2	64.7	3.73 ^b	.06
During RT stimuli	71.2	63.7	3.33 ^a	.08
Maximum HRs				
Pretone	83.2	76.7	2.42 ^a	.13
Posttone	86.1	80.2	2.08 ^a	.16
Pre-RT trials	81.2	76.2	1.46 ^b	.24
During RT stimuli	80.7	77.3	.63 ^b	.43

Note. Discrepancies in degrees of freedom are due to missing data. HR = heart rate; RT = reaction time.

^a $df = 1, 36$.

^b $df = 1, 35$.

^c $df = 1, 33$.

tion of either diagnosis or treatment. Although the combined analysis showed significant main effects for sessions and for trials, the separate analyses on the two populations indicate that this effect was only significant for the nonpatients. Patients did not habituate over trials on this measure, but nonpatients did. The Diagnosis \times Session interaction, which reflects the difference between habituation rates among the two populations in the combined analysis, was significant at $p < .005$ for the reaction time "get ready" stimuli.

Heart Rate

Tonic heart rate was measured every 15 sec during the rest periods and immediately before each trial during the loud tones and the reaction time task. There were no significant effects for treatment. However, the main effect for diagnosis was significant for *minimum* heart rates in the epochs following the loud tones and approached significance ($p < .07$ and $p < .08$) for minimum heart rates at other times (Table 4). This indicates that patients had higher "floor" heart rates than nonpatients. Although the pattern was similar for *maximum* heart rates in each epoch, the p values were much higher ($p < .2-.5$), thus strongly suggesting that peak heart rates were unaffected by anxiety neurosis.

Heart rate accelerations to the tones and reaction time stimuli were assessed by subtracting the maximum prestimulus heart rate from the maximum poststimulus heart rate. This adjustment was used to control for the effects of sinus arrhythmia, which otherwise would obscure the effects of reactivity to the tones. It was used rather than the traditional calculation of the difference between heart rate at stimulus onset and poststimulus maximum or minimum levels (uncorrected for prestimulus variability) because of experience from a prior study on the effects of alcohol on cardiac reactivity (Lehrer & Taylor, 1974). That study also used loud 1-sec long noxious tones. In Lehrer and Taylor (1974), the heart rate accelerations and decelerations corrected for prestimulus maximum and minimum levels differentiated between drunk and sober conditions, whereas the uncorrected accelerations and decelerations did not. Drunk subjects

showed greater corrected decelerations and smaller corrected accelerations in response to the five loud tones. Cardiac accelerations may be interpreted as components of a defensive reflex, and cardiac decelerations, as components of an orienting reflex to the stimuli (Graham & Clifton, 1966).

Accelerations

The differences between treatment groups in the first session (Table 2) were not significant. Cardiac accelerations elicited by the loud tones habituated significantly over trials (Table 3). Also, relaxation significantly enhanced habituation of this reflex over sessions, but only among the patient groups (see Tables 2 and 3 and Figure 1). There were no significant differences between groups for cardiac accelerations to the reaction time task.

Decelerations

The differences between treatment groups in the first session (Table 2) were not significant. Cardiac decelerations increased over sessions among the nonpatients but not among the patients. Significant treatment effects on the covariance-adjusted session-difference scores were obtained for the reaction time trials in the combined analysis and among the nonpatients. This effect was of borderline significance for the patients. Assuming that progressive relaxation would produce greater generalization to heart rate than alpha feedback, a linear trend analysis was done between groups of nonpatients, with the relaxation group assigned a value of 1, the alpha feedback group a value of 2, and the control group a value of 3. Significant linear trends were found for the tones ($p < .05$) and for the reaction time trials ($p < .02$), indicating that this effect was greater in the relaxation group, least in the control group, and at an intermediate level in the alpha feedback group.

Skin Conductance

Tonic Levels

Skin conductance was measured every 15 sec during the rest periods and immediately

before each trial during the loud tones and reaction time task. At each of the periods studied, skin conductance appeared to decrease over sessions in the relaxation group and to increase in the control group. The effects appear to be more pronounced among the patients than among the nonpatients, but they are at best, of only borderline significance (Table 3). Overall habituation across sessions was significant for the nonpatients but not for the patients.

Reactivity

The maximum skin conductance level during each epoch was scored and submitted to analysis. The differences between treatment groups (Table 2) in the first session were significant ($p < .04$) for the reaction time ready stimuli and the end-of-session rest periods in the combined analysis of relaxation and no treatment for patients and nonpatients. They were not, however, significant in either analysis of the diagnostic groups taken separately. The pattern of results was the same as that for tonic levels of skin conductance, but this time the covariance-adjusted treatment effects were significant for the patients (Tables 2 and 3, Figure 1). These results indicate that although the nonpatients tended to habituate over sessions regardless of treatment, the patients only habituated when treated. All subjects, however, significantly habituated over trials (within sessions) to the tones and reaction time task. The tendency of this measure to decrease more after relaxation instructions than after alpha feedback was only of borderline significance. The linear trend across groups, computed as described above for cardiac accelerations, approached significance during the end-of-session rest ($p < .13$) and during the reaction time trials ($p < .07$).

Frequency of skin conductance responses was also analyzed. During the rest periods at the beginning and end of each session, skin conductance increases of greater than 1% of the prestimulus skin conductance were tallied. The reciprocal transformation rendered these scores normally distributed. There were no significant effects on this measure.

Another measure of electrodermal reactivity

that was studied is the amplitude of the skin conductance responses elicited by the loud tones and the reaction time task. This was defined as the difference between the skin conductance at stimulus onset and the maximum skin conductance reached during the 15 sec following each loud tone or during the get ready stimulus for each reaction time trial. A log transformation rendered this measure normally distributed. The skin conductance response habituated significantly over sessions and over trials for the loud tones and the reaction time task. Also, a significant ($p < .05$) Session \times Trials interaction revealed that subjects habituated more quickly in the second testing session than in the first during the loud tones. The patients made a larger response to the first loud tone than the nonpatients, but otherwise the responses to the tones were similar for the two groups. The Diagnosis \times Trial interaction was significant at $p < .02$. On the other hand, the patients emitted significantly ($p < .02$) smaller responses to the reaction time task than the nonpatients. There were no significant effects or interactions involving the treatment factor.

A third measure of electrodermal reactivity was recovery rate of the skin conductance response. Edelberg (1972) has found that stress and threat of stress slow the recovery of the skin conductance response and that schizophrenic patients show slower recovery than normal subjects (Maricq & Edelberg, 1975). He has also demonstrated that the recovery rate can be approximated by measuring the percent recovery during the 2 sec following the apex of each response (Edelberg, Note 3). We computed this measure for the first observable skin conductance response emitted after each loud tone and after the onset of each get ready stimulus for the reaction time task. The log transformation rendered these data normally distributed. Log percent recovery increased significantly over trials during the loud tones. This parallels the findings for cardiac accelerations and appears to reflect a habituation of the defensive reflex over trials. However, there were no significant effects involving diagnosis, treatment, or session.

Reaction Times

The natural log transformation rendered the reaction time data normally distributed. There were no significant effects for treatment, diagnosis, or the interactions of these with sessions.

Discussion

Relaxation Effects

Relaxation appeared to reduce physiological reactivity. This finding was most pronounced among the patients, for whom relaxation was significant for maximum skin conductance elicited by both tasks, for cardiac accelerations (defensive reflexes) elicited by the loud tones, and for percent alpha levels after the loud tones. The effect was not present for measures of tonic physiological activity. This supports the notion that progressive relaxation of the muscles generalizes to relaxation in other physiological systems. It also confirms the findings reviewed above that physiological effects of brief relaxation instructions can best be measured in an anxious population. The reason for this appears to be different for each of the three measures on which significant effects were found. For maximum skin conductance after the stimuli, the nonpatients all appeared to habituate over sessions, whereas the patients only habituated when they had been taught relaxation. For cardiac accelerations to the loud tones, subjects tended to sensitize over sessions rather than to habituate, although this overall effect was not significant. The patient population appears to have been more prone to this sensitization effect than the nonpatients, and this effect was attenuated only by relaxation training. After training, the patients' pattern of autonomic reactivity became similar to that of the nonpatients. For percent alpha after the loud tones, the results are more complex. Percent alpha was significantly increased by relaxation among the patients. However, the nonpatient relaxation group had a seemingly paradoxical decrease in percent alpha, rather than an increase. One can only speculate on possible causes for this. The patient control group showed this same pattern, and the latter

group apparently sensitized over sessions. It is possible that something similar happened to the nonpatient relaxation group, but this would be inconsistent with the data on autonomic functions. Perhaps the nonpatient relaxation group was emitting theta activity. The tape-recorded data were no longer available for checking this, but a cursory examination of the raw data indicate that this was not so. Another possibility is that the nonpatients were "working too hard" at relaxing and were concentrating on their muscles so much that alpha was blocked. I have informally tried concentrating on relaxing my own muscles while being given alpha feedback and have similarly experienced a decrease in alpha production. But why, then, did this not happen with the patient relaxation group? Here we must speculate some more. Perhaps the patients had taken the task more seriously and had practiced more intensively at home. Thus, when they came for testing, the task could have been more automatic for the patients than for the nonpatients. Informal contacts with the subjects indicated that patients were more motivated to practice the task than nonpatients, since they expected some therapeutic benefit.

There are two measures on which the relaxation effects were somewhat more pronounced among nonpatients than among patients: cardiac decelerations (orienting reflexes) to the reaction time task and state anxiety. The slightly greater treatment effects among nonpatients for cardiac decelerations may partly be a mathematical artifact of changes in cardiac accelerations and partly a reflection of the higher heart rate "floor" for the patients, perhaps due to their higher state of general sympathetic tuning. Relaxation apparently did not affect heart rate floors. In a previous study we found that alcoholics also have higher floor heart rates than "normal" subjects (Lehrer & Taylor, 1974), and we interpreted this as reflecting changes in cardiac function due to chronic alcohol intake. It is possible that the effect in the present study was also due to drug intake in the patient group, since most of the patients in the sample had histories of taking tranquilizers. It is also possible that the results of both

studies are due to the effects of chronic anxiety in both patient groups. Perhaps chronic anxiety inhibits the individual from emitting orienting reflexes to situations that had previously evoked defensive reflexes. This "shift" would be expected to occur over time among normal individuals (Sokolov, 1963). In this regard, note also that cardiac decelerations (orienting reflexes) to the loud tones increased significantly over sessions in the nonpatients but not in the anxious patients (Table 3).

The fact that state anxiety was decreased by relaxation more among the nonpatients than among the patients may result from the fact that many of the patients showed obvious evidence of "secondary gain" from their symptoms, including having a friend, parent, or spouse accompany them to each session because of their fears. To admit that their fear was reduced during the testing sessions would have justified their giving up this dependence.

Relaxation, Alpha Feedback, and Generalization

As revealed in the trend analyses on the nonpatients, alpha feedback produced greater increases in alpha but smaller changes in other physiological measures and subjective anxiety than progressive relaxation. These findings give some support to the notion of physiological specificity of alpha. These results are also consistent with the findings of Orne and Paskewitz (1974) that increases in alpha produced by alpha feedback do not generalize well to other physiological functions or to subjective anxiety. Muscle relaxation appears to produce greater generalization.

Physiological Activity Versus Reactivity

It should be noted that relaxation effects were more pronounced for measures of physiological reactivity than for measures of tonic physiological activity. They were greater for maximum skin conductance level for each epoch than for initial skin conductance level in the epoch, greater for cardiac accelerations and decelerations than for tonic heart rate, and greater for percent alpha in the pe-

riod following the loud tones than at any other time period. In terms of Routtenberg's (1968) hypothesis of two separate arousal systems, perhaps progressive relaxation has greater effects of the type of arousal mediated by the limbic system than that mediated by the reticular system.

Other Differences Between Patients and Nonpatients

Another finding of interest is that the patients appeared to be hyperresponsive to threat but somewhat underresponsive to a nonthreatening task, which generally produces an orienting reflex rather than a defensive reflex. The patients emitted larger skin conductance responses to the first loud tone and higher scores on the STAI at the beginning of each session than the nonpatients, but the patients emitted smaller skin conductance response amplitudes during the reaction time task than the nonpatients. Apparently, patients respond with greater extremes of electrodermal reactivity than do the nonpatients, giving smaller responses to the nonthreatening reaction time task (which requires orientation to the environment rather than defense from it) but a larger response to the threatening first loud tone. This squares with the clinical picture of anxiety neurotics as easily upset by everyday stress and not always as "tuned in" to their environment because of their anxious preoccupations.

Finally, Lader and Wing's (1966) contention that people suffering from anxiety neurosis habituate more slowly than nonpatients to noxious stimuli is lent some support by this experiment. Patients showed less habituation of alpha blocking and skin conductance levels than did nonpatients.

Objective Measurement of Fear of Success and Fear of Failure: A Factor Analytic Approach

Susan Sadd, Michael Lenauer, Phillip Shaver, and Noel Dunivant
New York University

Several objectively scored measures of fear of success and fear of failure have been designed in recent years, but there is little evidence that they measure two distinct, unidimensional constructs. The present study was undertaken primarily to answer two questions: Are fear of success and fear of failure operationally distinct? Do all fear of success measures tap a single unidimensional construct? Eight fear of success and fear of failure scales were administered to 415 male and female subjects, and the scores were intercorrelated. Results indicated that fear of success is not a unidimensional construct and that some of the measures of fear of success and fear of failure are highly related. Next, each scale was factor analyzed, and 37 new variables were created. These were in turn factor analyzed, and five highly stable orthogonal factors were obtained. One of these factors appears to be fear of success; another is clearly test anxiety (called fear of failure in the literature on achievement motivation). A third factor is concerned with sex-role-related attitudes toward success in medical school. A fourth seems to reflect neurotic insecurity, and the fifth has to do with the value of success. Indices of psychological well-being and psychosomatic illness related differently to each of the five factors. Implications and further questions are discussed briefly.

Horner's research on fear of success (Horner, 1969a, 1969b, 1972, 1974) has generated well over 100 research articles in the past few years. According to Horner (1969a), fear of success (hereafter FOS) is "the fear that success in competitive situations will lead to negative consequences" (p. 38). Taken by itself this definitional phrase is quite general. However, because Horner was primarily interested in a form of FOS that she thought was characteristic of females in American

society, she included in her definition not only general negative consequences of success, such as social rejection ("unpopularity"), but also "loss of femininity." Most subsequent studies have failed to support this specific definition, however. In a recent review of the burgeoning literature on fear of success, Tresemer (1976) concluded that the "hypothesis that there is a gender difference in FOS is not supported" (p. 217). Therefore, the more general definition of FOS, leaving out loss of femininity, appears to be the most appropriate starting point for anyone undertaking studies in this area. Unfortunately, interested researchers will find little consensus concerning the best way to measure FOS. The present article takes a few steps toward remedying that problem.

Horner's earliest measure of FOS, and the one used most often by subsequent researchers, was a Thematic Apperception Test (TAT) type of projective device based on the following story line: "After first term finals

The research reported here was supported in part by a grant to Phillip Shaver from the Spencer Foundation, administered through Columbia University's Teachers College, and in part by a grant to Phillip Shaver and Katherine Garner from New York University. The authors are grateful to Katherine Garner and Caryl Dobrer for help in early phases of the study.

Anne (John) finds herself (himself) at the top of her (his) medical school class." Subjects were asked to complete the story by describing Anne or John in more detail, including how she (he) felt about this situation and what would probably happen in the future. This measure is problematic for several reasons. It is highly specific to a set of circumstances—success in medical school—which is obviously not synonymous with success in general. Moreover, until recently, American medical schools were masculine institutions, which meant that the hypothetical Anne was not only successful in a general sense but also highly deviant for her gender in terms of career choice (Lockheed, 1975). Add to this the fact that males were given the John cue and females the Anne cue, and it is easy to see that fairly specific attitudes about a successful male or female *in medical school* were being tapped, not necessarily a general personality trait, FOS. Finally, a present/absent scoring system based on one such story is not likely to be reliable (cf. Nunnally, 1967).

Because of these and other problems, many new measures of FOS have been developed recently, one by Horner and her colleagues (Horner, Tresemer, Berens, & Watson, Note 1) and several by other investigators (e.g., Cohen, 1975; Good & Good, 1973; Pappo, 1973; Spence, 1974; Zuckerman & Allison, 1976). Shaver (1976) reviewed the measures briefly and raised several questions about them. First, are all of the instruments measuring the same thing? The answer is almost certainly no. With some of the measures (e.g., Good & Good, 1973; Spence, 1974; Zuckerman & Allison, 1976), significant sex differences have been obtained, but this is not the case with other measures (Cohen, 1975; Pappo, 1973). Even more disturbing, the sex difference between means is not always in the same direction for different measures; Spence's instrument reveals more hostility among males toward a successful male, for example. Also disturbing are the low correlations between some of the new measures (e.g., Zuckerman & Allison, 1976) and Horner's original one, even though these are purported to measure the same construct.

A less familiar but even more serious problem is that FOS may not be different from what achievement motivation researchers (e.g., Atkinson & Feather, 1966) have called fear of failure. Shaver (1976) argued that most of the experimental results obtained by Cohen (1975), Pappo (1973), and Zuckerman and Allison (1976), which these authors interpreted as evidence for the construct validity of their FOS measure, could have been explained just as easily in terms of fear of failure. Compatible with Shaver's argument is the highly significant correlation of .57, which Pappo reported between her measure and the Debilitating Anxiety scale of the Achievement Anxiety Test (AAT; Alpert & Haber, 1960), a commonly used measure of fear of failure. Jackaway and Teevan (1976) compared the new FOS measure developed by Horner et al. (Note 1) with the projective measure of fear of failure devised earlier by Birney, Burdick, and Teevan (1969) and found significant correlations between the two measures for both males and females (.42 and .57, respectively). This finding is not surprising given the considerable overlap between the two scoring systems.

Believing that much of the inconsistency and confusion in the recent FOS literature is due to measurement problems, we undertook a factor analytic study of several measures of FOS and fear of failure. The study was designed primarily to answer two questions: (a) Are FOS and fear of failure measurably distinct? (b) To what extent do the recently devised objective tests of FOS measure a unitary (i.e., unidimensional) construct? To begin exploring another issue raised by Shaver (1976)—namely, that avoidance motives proposed in the achievement literature might be related to psychosomatic and psychological symptoms of conflict and stress, in addition to or instead of, being related to performance decrements—we also included questions concerning these symptoms.

The present article focuses only on objectively scored measures of FOS and fear of failure, because these are likely to be more reliable and are obviously easier to administer and score. Further research will be necessary to discover whether one or more of the di-

mensions we discovered are present in the projective measures as well. We did, however, include one measure that is directly related to Horner's original TAT-like device, Spence's (1974) objectively scored version of the Anne/John cue.

Measures Included in the Factor Analysis

Before presenting our study in detail, each measure will be described briefly. Five measures of FOS and two measures of fear of failure were included.

Spence (1974). The objective measure of FOS most similar to Horner's original projective measure is the one developed by Spence, which requires that subjects complete three stories, including the one about Anne (or John) in medical school, and then answer a series of multiple-choice questions about the story. For the Anne story these questions include: "How likable do Anne's classmates consider her?" In a study of 328 male and female undergraduates, Spence (1974) found a significant relationship between her measure and Horner's. Other analyses led Spence to conclude that her measure, as well as Horner's, tapped attitudes toward certain kinds of achievement rather than a deeply rooted personality trait. It is also worth mentioning, because we replicated Spence's results, that she found males to be more negative toward a successful male than females were toward a successful female. Although this is quite different from what Horner (1969b) would have predicted, it is compatible with many studies based on Horner's measure (Tresemer, 1974, 1976).

In the research to be reported here, we used the Anne (or John) story lead followed by 15 of Spence's multiple-choice questions.

Good and Good (1973). These authors developed a 29-item self-report measure of FOS based on Horner's (1969a, 1969b) notion that a person who fears success will be anxious and worried about other people's negative reactions to her (or his) success. In a sample of 228 male and female college undergraduates, the mean FOS score for females was significantly higher than the mean score for males, as Horner expected. The measure contains items of the following sort, each of

which is answered on a true-false scale: "I worry that I may become so knowledgeable that others will not like me." "If I were to do well at something, I would worry that someone might try to undermine my success."

Zuckerman and Allison (1976). These authors' 27-item scale contains statements concerning (a) benefits of success, (b) costs of success, and (c) attitudes toward success as compared with other alternatives. It was constructed on the basis of Horner's theorizing. The following items, answered on a 7-point agree-disagree scale, are representative: "The cost of success is overwhelming responsibility." "When competing against another person, I sometimes feel better if I lose than if I win." Based on Horner's description of FOS, Zuckerman and Allison predicted that FOS would be greater for females than for males, and in three different samples of undergraduate college students, females scored higher than males. (The difference was statistically significant in two out of three samples.) In two of their samples, Zuckerman and Allison's scale correlated weakly but significantly with Horner's (1969b) measure. In a validation study, high-FOS subjects performed significantly less well on an anagrams task than did low-FOS subjects.

Pappo (1973). The measures developed by Pappo (1973) and Cohen (1975) are different in conception from the ones described thus far. Whereas Horner, Spence, Good and Good, and Zuckerman and Allison were all interested in a motivational construct related to sex role socialization, Pappo and Cohen were interested in a neurotic form of FOS that might be equally prevalent among males and females. The two researchers differed slightly in their conceptualization of the etiology of neurotic FOS, with Pappo favoring Sullivanian theory (Sullivan, 1953) and Cohen basing her conception on Freud's discussion of oedipal conflicts.

Pappo developed an 83-item true-false questionnaire to measure "academic fear of success." The scale has been administered to large samples of high school and college students, and as expected no sex differences have been found. In an experimental study involving college students (Pappo, 1973), high

scorers on the scale exhibited poor performance on a reading test following success feedback; low scorers, in contrast, improved. The following are typical items from Pappo's scale: "I feel I need someone to push me to do the things I want to do." "I find it difficult to measure up to the standards I set for myself."

Cohen (1975). Cohen used Pappo's (1973) scale as a model; consequently, many of the items in the two scales are quite similar, although Cohen's are more general (i.e., not tied to academic situations). In a high-ability, achievement-oriented sample of high school students, Cohen's 64-item true-false scale successfully predicted which subjects would perform poorly on a memory task following success feedback. (Both Pappo's and Cohen's scales can be found in Canavan-Gumpert, Garner, & Gumpert, 1977.)

Measures of fear of failure. We included two measures of test anxiety or fear of failure, the Test Anxiety Scale (TAS) used in many studies by Sarason (e.g., 1972, which includes the scale items) and the AAT, designed by Alpert and Haber (1960) within the framework of achievement motivation theory (Atkinson & Feather, 1966). The TAS is a 37-item true-false scale. The AAT contains two subscales, one measuring debilitating anxiety (10 items, hereafter referred to as AAT-) and the other measuring facilitating anxiety (9 items, AAT+); both refer explicitly to academic or intellectual testing situations. The following items are typical of the TAS and the AAT-: "While taking an important exam I find myself thinking how much brighter the other students are than I am." "Nervousness while taking an exam or test hinders me from doing well." (The AAT+ is not important to later conclusions; essentially, it measures a form of arousal in test situations that is negatively correlated with debilitating test anxiety.)

Overview of the Present Study

We administered all of the measures described above to 415 university students; in addition, each subject provided background information and answered questions concerning psychological problems and psychosomatic

symptoms. Analysis of the data proceeded in stages. First, the reliabilities of the scales were computed for our sample, and, since these were acceptable, mean scores for males and females were compared. Second, the scales were intercorrelated, separately for males and females, to determine how strongly they related to each other. Third, each scale was factor analyzed, and 37 subscales were created. These subscales were in turn factor analyzed, yielding five orthogonal factors. Finally, scores on these five factors were correlated with background variables and measures of psychological well-being.

Method

Subjects

A letter was sent in the spring of 1976 to juniors and seniors at New York University inviting them to participate in a study of "achievement-related motivation and career choice." Older students were preferred, because they were closer to graduation and career choice, and thus to real-world success or failure. To obtain a sufficiently large sample, subjects were also recruited in classrooms and dormitory lobbies. Each subject received \$3 for filling out the battery of questionnaires. Data were collected from 430 subjects, but 15 of these failed to follow instructions or left out large numbers of items. Thus, 166 males and 249 females ($N = 415$) were represented in the data analyses.

Materials and Procedure

Each subject received a large envelope containing a background information form and two booklets of questions (Parts 1 and 2). Included in the background information form were standard demographic questions, questions about the subject's relationship with his or her parents, and a list of psychological problems and psychosomatic symptoms. Part 1 contained Horner's (1969b) medical school cue, followed by Spence's (1974) objective questions. (Females wrote about Anne in medical school; males, about John.) Instructions were the same as Horner's, except for a request that subjects were not to look at the multiple-choice questions following the story until after the story had been completed. Part 2 contained questions from the objective measures of FOS and fear of failure (Alpert & Haber, 1960; Cohen, 1975; Good & Good, 1973; Pappo, 1973; Sarason, 1972; Zuckerman & Allison, 1976). The items from all six measures were shuffled and printed in random order, and all were answered on a 4-point scale from strongly disagree, disagree, agree, to strongly agree. For items worded in the FOS or fear of failure direction, strongly disagree was

scored as 1; disagree, as 2; agree, as 3; and strongly agree, as 4. For items worded in the opposite direction (to control for acquiescence response bias), scoring was reversed. Scale scores were obtained by summing across items.

Data Analysis

Because of the complicated nature of the analyses to be reported, each stage of the analysis and its results will be described and discussed in turn. General discussion will be reversed until all analyses have been presented.

Results

Phase 1: Analyses Involving the Original Scales

Because scoring of the scales was modified slightly in the present study, so that all questions could be answered on the same 4-point continuum, internal-consistency reliability coefficients were computed (see Table 1). Since the number of items differs from scale to scale, estimated reliabilities for tests of standard length (20 items) were computed using results from the present study. This allows for comparison of the reliabilities of the various scales. These estimated reliabilities are also presented in Table 1.

Some of the scale constructors, following Horner (1969b), predicted sex differences in FOS (Good & Good, 1973; Spence, 1974; Zuckerman & Allison, 1976); others did not (Cohen, 1975; Pappo, 1973). In the present study, the only measure that produced a significant difference between males and females was Spence's measure of FOS. The results of the Spence questionnaire were similar to those reported by her in 1974; males showed significantly higher FOS than females. (Standard scores were computed for each of the 15 items on the Spence scale. These standard scores were summed to yield a total scale score for each subject; scores ranged from -15.17 to 28.58.) Means, standard deviations, and *t* tests are summarized in Table 2.

Of major interest in this study were the relationships among the various instruments used to measure FOS and fear of failure. A matrix of correlations among the eight scales was obtained separately for males and females. As can be seen by comparing the val-

Table 1
Reliabilities of the Original Scales for the Present Sample

Item	Coefficient α	Reliabilities of a 20-item scale
Fear of success		
Spence (1974)	.83	.87
Good & Good (1973)	.89	.84
Zuckerman & Allison (1976)	.68	.61
Pappo (1973)	.90	.69
Cohen (1975)	.92	.78
Fear of failure		
Debilitating scale	.84	.91
Facilitating scale	.64	.80
Test Anxiety Scale	.91	.85

ues for males and females in Table 3, there are very few differences between the corresponding correlations for the two sexes. A number of interesting relationships appeared for both males and females. For ease of understanding, these will be discussed under three separate headings: (a) relationships among two or more FOS measures; (b) relationships among the fear of failure measures; and (c) relationships between FOS and fear of failure. Each group of relationships will be discussed in turn.

1. Spence's (1974) measure of FOS correlated most strongly with the measure developed by Zuckerman and Allison (1976). ($r_t = .41$; $r_m = .37$; the subscripts *f* and *m* refer to males and females.) This finding is quite reasonable given that both Spence and Zuckerman and Allison designed their measures with Horner's work in mind. Nevertheless, the two measures are quite different in design and item format, so it is not surprising that the correlations between the two scales were not higher. It is impossible to determine the extent to which method variance, as distinct from differences in content, contributed to lowering these correlations.

The correlation between Pappo's (1973) and Cohen's (1975) measures approached the reliabilities of the scales ($r_t = .88$; $r_m = .86$). The correlations between Pappo's measure and other variables were quite similar to the

Table 2

Mean Scores and Standard Deviations for Males and Females on the Original Scales

Item	Males		Females		<i>t</i>
	<i>M</i>	<i>SD</i>	<i>M</i>	<i>SD</i>	
Fear of success					
Spence (1974)	2.47	8.12	-2.15	7.58	5.71*
Good & Good (1973)	61.28	10.53	59.83	11.08	1.29
Zuckerman & Allison (1976)	64.57	7.06	64.65	6.27	0
Pappo (1973)	197.40	20.72	196.74	22.81	.09
Cohen (1975)	157.90	18.83	157.80	20.39	0
Fear of failure					
Debilitating scale	22.93	4.72	23.53	4.97	1.20

* $p < .001$; all other *t* tests were nonsignificant.

correlations between Cohen's measure and those same variables. According to Pappo and Cohen, their conception of FOS is quite different from Horner's, a claim that is supported by the relatively low correlations between the Pappo and Cohen measures on the one hand and the measures developed from Horner's theory (Spence, 1974; Zuckerman & Allison, 1976) on the other. For example, Pappo's scale correlated .39 for females (.41 for males) with Zuckerman and Allison's scale: $r_t = .30$ with the measure designed by Spence ($r_m = .27$).

Good and Good's (1973) scale appears to measure elements common to the Horner-based scales and the measures designed by Pappo and Cohen. The correlations between FOS as measured by Good and Good and either the Horner-based measures or the Pappo and Cohen measures were higher than

any correlation between a Horner-based measure and Pappo's or Cohen's scale. Apparently, the Good and Good measure shares some content with both kinds of FOS measures.

2. The two measures of fear of failure, TAS and AAT—, were highly correlated with each other ($r_t = .83$, $r_m = .78$), thus replicating the findings of earlier investigators (Alpert & Haber, 1960; Sarason, 1960). The relationships between the TAS and other measures were nearly identical to the correlations between the AAT— and those same measures, which lends support to the contention that the TAS and AAT— measure the same construct. The AAT+ correlated negatively with the TAS and AAT— at about the level reported by Alpert and Haber (1960).

3. As mentioned earlier, some authors have suggested that FOS and fear of failure are indistinguishable motives (Jackaway & Tee-

Table 3

Correlations Among Eight Original Scales

Item	1	2	3	4	5	6	7	8
1. Spence (1974)	—	.36	.41	.30	.26	.24	.06	.25
2. Good & Good (1973)	.28	—	.67	.64	.64	.54	-.06	.50
3. Zuckerman & Allison (1976)	.37	.48	—	.40	.39	.29	-.06	.28
4. Pappo (1973)	.27	.69	.40	—	.88	.70	-.16	.69
5. Cohen (1975)	.27	.67	.48	.86	—	.66	-.24	.68
6. Debilitating scale	.19	.53	.20	.66	.62	—	-.40	.83
7. Facilitating scale	-.05	-.16	-.22	-.33	-.34	-.45	—	-.41
8. Test Anxiety Scale	.08	.50	.17	.62	.58	.78	-.46	—

Note. Correlations above the diagonal are for females ($n = 249$); those below the diagonal are for males ($n = 166$). For $n = 249$, $r_{.05} = .16$; for $n = 166$, $r_{.05} = .19$.

van, 1976; Shaver, 1976). The Pappo (1973) and Cohen (1975) measures correlated quite strongly with the measures of fear of failure, but the Horner-based measures did not. Since the latter are based on the notion that FOS develops through sex role socialization, one would not expect the Horner-based measures of FOS to be related to fear of failure. Nor would one expect them to be related if the Horner-Spence measure is tapping attitudes about success in medical school rather than fear of success.

Our examination of the correlations among the scales suggests that FOS is not unidimensional and that there is considerable commonality between FOS and fear of failure as they are currently operationalized. A factor analytic study is needed to reveal the basic underlying dimensions that have until now been confused.

Phase 2: Factor Analyses

To conduct a reliable factor analysis of 254 items, about 1,300 subjects would be needed, and this number was beyond our resources. Therefore, an alternative two-step procedure was followed: First, each of the eight scales (treating AAT+ and AAT- as separate scales) were factor analyzed; next, the resulting factor scores were factor analyzed. Since only 37 factors resulted from the first step of this procedure, it was possible to produce very stable factors in the second step using data from 415 subjects.

First-order factor analysis. Each of the eight scales was factor analyzed using a principal components analysis with communalities in the diagonal. (This and all other procedures followed in the study have been described by Gorsuch, 1974.) The number of factors extracted from each scale was determined using multiple criteria: the scree test, percent of variance accounted for, and interpretability. The extracted factors were rotated to the direct oblimin criterion.¹ An item with a factor loading greater than .30 was selected as an item representing that factor. When an item loaded significantly on two or more factors, the differences between loadings were tested for significance. If the difference was not significant, the item was assigned to

both factors in question. In the few cases in which items did not load significantly on any factor, they were eliminated from later analyses.

The first-order factor analysis yielded 9 factors for Pappo's (1973) scale, 4 for Zuckerman and Allison's (1976), 4 for Good and Good's (1973), 8 for Cohen's (1975), 6 for the TAS, 1 for AAT-, 1 for AAT+, and 4 for Spence's measure; thus, a total of 37 new variables were created.

Second-order factor analysis. Scores for each subject were computed on the 37 factors identified in the first-order factor analyses. All items that loaded .30 and above were assigned unit weights and were summed to produce total scores. To evaluate the stability of the factor solution, subjects were randomly assigned to two separate subsamples (Data Sets 1 and 2, or DS-1 and DS-2). Since there were significant mean differences between male and female scores on 2 of the 37 factors (1 from Spence's measure and 1 from Pappo's), within-groups correlations were computed for the two subsamples as recommended by Cooley and Lohnes (1971). Following an initial principal components analysis of the within-groups correlation matrix for DS-1, which produced a six-factor solution, the analysis was repeated specifying that it produce three-, four-, and five-factor solutions, each followed by both oblique and orthogonal (varimax) rotations. The choice of the final solution, 5 orthogonal factors, was based on clarity and interpretability.

To determine the degree of stability of the factor structure from DS-1, we attempted to replicate it using data from the second half of the sample (DS-2). A principal components analysis of the within-groups correlations for DS-2 was performed. Then, taking the varimax rotated factor structure matrix from DS-1 as the target matrix, the initial factor solution for DS-2 was subjected to an orthogonal Procrustes rotation (Cliff, 1966).²

¹ Factor analyses were computed using program FACTOR from the *Statistical Package for the Social Sciences* (Nie, Hull, Jenkins, Steinbrenner, & Bent, 1975).

² These analyses were conducted using VARAN 2, a linear model variance analysis program (Hall, Kornhauser, & Thayer, 1973).

That this procedure succeeded in generating highly congruent factor structures is evinced in the correlations between matching factors for the two data sets: .97, .98, .92, .85, and .84. Having replicated the five-factor solution, we recombined the data from the two halves of the sample and computed a final five-factor varimax solution using all 415 cases. Of course, the results of this analysis were virtually identical to the results for each half of the sample.

*The new scales.*³ The end result of the factor analytic process can be viewed as five new scales composed of items from the original measures of FOS and fear of failure. To understand the scales and their implications, one must know something about their composition and meaning.

Factor 1 is composed of first-order factors from the measures designed by Good and Good (1973), Zuckerman and Allison (1976), Pappo (1973), and Cohen (1975). We have named this factor *Concern about the Negative Consequences of Success*, because all of the items loading highly on it reflect concern about jealousy, exploitation, criticism, sabotage, rejection, burdensome responsibility, and pressure following success. Also represented on this factor are statements about feelings and behaviors that may result from such concern. The factor is characterized by the following sorts of items:

(a) If I were outstanding at something, I would worry about the possibility of others making fun of me behind my back, and (b) the cost of success is overwhelming responsibility.

Of the five factors, this one comes closest to the general definition of FOS offered by Horner (1969a): "fear that success in competitive situations will lead to negative consequences" (p. 38).

Factor 2 is composed solely of first-order factors from Pappo's (1973) and Cohen's (1975) measures. This factor has been labeled *Self-deprecation and Insecurity*, and it is characterized by failure to live up to one's own standards, self-consciousness, unassertiveness, and behavioral manifestations of insecurity. This factor includes items such as: (a) I frequently find it difficult to measure up to the standards I set for myself, and (b)

I often brood about something I've said which may have been taken the wrong way by another person. It is extremely important that none of the items on this factor explicitly mentions negative consequences of success, and therefore the factor may not represent fear of success at all.

Factor 3 is simply *Test Anxiety*. All six first-order TAS factors, plus AAT- and AAT+, load on this factor. None of the components of the other scales loads significantly on Factor 3. This is probably due in part to the extreme specificity of the situation described in the scales; all refer directly to anxiety in testing situations. Whether this factor deserves the more general label of fear of failure is disputable.

Factor 4 contains all of the first-order factors derived from Spence's measure of FOS, with no contributions from any other measure. This too is probably the result of the specificity of the situation described in the measure, which leads us to call it *Attitudes Toward Success in Medical School*. This designation is compatible with Spence's description of Horner's cue as a measure of attitudes rather than personality.

Factor 5 is called *Extrinsic Motivation to Excel*. Items on this factor are concerned with the extreme importance of success, status, and power. There is no mention of fear or negativity of success. The 19 items come from two factors of Zuckerman and Allison's (1976) scale and one factor from Pappo's (1973) scale; they include (a) When you're on top, everyone looks up to you, and (b) I feel that it is important for people of higher status to like me. Most of the items on this factor were written to reflect the absence or opposite of FOS; in fact, however, they seem to measure an independent dimension.

Phase 3: Relationships Between the Factors and Psychological Well-Being and Psychosomatic Symptoms

Five factor scores were computed for each subject using the varimax factor weights ob-

³ A complete list of items, factor loadings, and scoring procedures can be obtained from the authors on request.

tained in the factor analysis based on all 415 subjects. These scores were then correlated with demographic variables, family background variables, grade point average, and indices of psychological well-being including psychosomatic symptoms.⁴ The latter indices were based on a 4-point scale associated with the following question: "How much have the following problems bothered you during the past year?" (The alternatives were not at all, a little bit, moderately, and quite a bit.) We expected the first three factors—Concern over Negative Consequences of Success, Self-deprecation and Insecurity, and Test Anxiety—to be related to psychological and psychosomatic symptoms, since all of them involve anxiety or conflict. This should be especially true for the Self-deprecation factor, which is very similar to measures of general anxiety or neurosis. We did not expect Factor 4, Attitude Toward Success in Medical School, to be related to psychological well-being, although Horner's (1969b, 1974) original work might have led some investigators to expect this. Factor 5, Extrinsic Motivation to Excel, might be related to a few symptoms of stress, since it connotes great drive and ambition, but there is no certain basis for this prediction. (Factor 5 was unanticipated and is still the least well understood of the five factors.)

The criterion for considering a correlation coefficient as meaningful was set at .20. Although small, a correlation of this size is highly reliable ($p < .001$). All correlations above .20 are shown in Table 4.

As expected, Factor 4 (Attitudes Toward Success in Medical School) was not correlated with any of the psychological or psychosomatic variables. Factor 5, Extrinsic Motivation to Excel, was correlated with only two items, both indicating sleep disturbances. Also as expected, Factor 2, Self-deprecation and Insecurity, was related to the largest number of problems and symptoms (14) and yielded the largest correlation coefficients. Notice that the highest correlation in this list is the one between Factor 2 and feelings of worthlessness, which is quite consistent with the label assigned to the factor Self-deprecation and Insecurity. Test anxiety (Factor 3) was

Table 4
Correlations of Factors with Psychosomatic Symptoms

Symptom	Factor			
	1	2	3	5
Headaches				.20
Feeling tired or low in energy		.36		
Poor appetite	.20			
Crying easily		.20	.21	
Feeling lonely		.39		
Worry and anxiety		.39	.23	
Irrational fears		.37	.21	
Nausea or upset stomach		.22		
Trouble falling asleep			.21	.22
Sleep that is restless or disturbed		.28	.28	.20
Waking up too early in the morning	.24			
Feeling tense or keyed up		.37		
Overeating		.25		
Feelings of worthlessness		.53	.29	
Feelings of guilt		.40	.24	
Trouble concentrating		.40	.34	
Feeling that you just can't go on	.26	.31	.30	
Difficulty making decisions		.43		

Note. None of the correlations with Factor 4 exceeds .20. The following symptoms did not correlate above .20 with any factor: faintness or dizziness; loss of sexual interest or pleasure; stomach ulcers or colitis; pains in heart or chest; pains in lower back; recurring diarrhea; chronic constipation; high blood pressure; trouble getting your breath.

also correlated with several psychosomatic and psychological problems, although not as many as were related to Factor 2. The fact that the highest relationship was between test anxiety and poor concentration is quite compatible with previous research on test anxiety (e.g., Sarason, 1972; Wine, 1971). Factor 1, Concern over the Negative Consequences of Success, which we have said seems closest to Horner's original conception of FOS, was also related to three psychological and psychosomatic problems: poor appetite, waking up too early in the morning, and feeling that one "just can't go on." Perhaps it is worth mentioning that all three are common symptoms of depression.

⁴ Correlations with demographic and background variables will not be discussed in this article. A list and discussion of the significant relationships can be obtained from the authors.

Discussion

We began with two major questions: (a) Are all of the recently proposed objective tests of FOS measuring the same unidimensional construct? and (b) Are FOS and fear of failure measurably distinct? The answer to the first question is no. The answer to the second question is more complex. FOS as measured by Pappo (1973) and Cohen (1975) is closely related to measures of test anxiety (fear of failure), but FOS as measured by Spence is not.

Seeking clearer answers to our two major questions, we factor analyzed each of the original scales, producing 37 new variables. These variables were then factor analyzed, and five orthogonal factors were produced. One of these, Factor 3, was clearly Test Anxiety; all components of the original test anxiety scales (TAS, ATT+, and ATT-) loaded on this factor, but no other variables did. If one agrees with achievement motivation researchers that test anxiety should be called "fear of failure," then Factor 3 represents fear of failure. We are hesitant to accept this general label, however. The items on Factor 3 are quite specific to academic or intellectual tests and may not be good indicators of fear of failure in other situations.

Factor 2, which we have called Self-deprecation and Insecurity, might serve as a more general measure of fear of failure. The items reflect fear that the person cannot or will not live up to his or her own standards. Some of the items refer explicitly to low self-confidence and anticipation of failure. As defined by achievement-motivation researchers, fear of failure (or the "motive to avoid failure") is a "capacity to experience shame given non-attainment of a goal (failure)" (Weiner, 1972, p. 200). High scorers on Factor 2 surely display this capacity.

There are two obstacles to accepting Factor 2 as a general measure of fear of failure, however. First, many of the items that load highly on Factor 2 deal with neurotic inhibition of assertiveness; high scorers are afraid to express their desires or to stand out in a group. We do not know for sure whether this should be included in a general measure of fear of failure. Second, Pappo (1973) and

Cohen (1975) argued that FOS is unconscious and hence is expressed only indirectly; it may even manifest itself to the success-anxious person as fear of failure. This argument is weakened somewhat by our finding that the items that explicitly mention negative reactions to success load on Factor 1, not on Factor 2, which contains the largest portions of Pappo's and Cohen's scales. Still, we cannot completely rule out the possibility that Factor 2 measures unconscious fear of success. Only careful experimental studies can clarify this matter.

Factor 1, Concern over Negative Consequences of Success, fits very well with Horner's original conception of FOS, except that it does not include loss of femininity. Horner believed that FOS was significantly more prevalent in women than in men because it was the result of sex role socialization processes. According to the stereotypic image of males and females, independence, competence, intellectual achievement, and leadership are positive attributes for males, but they are inconsistent with femininity. In the present study, however, we found no sex differences in concern about negative consequences of success. Males are just as likely as females to exhibit concern over the negative consequences of success. None of the items that load on Factor 1 mentions conflicts with or loss of femininity. Rather, the concern is over jealousy, exploitation, social rejection, and excessive pressure and responsibility. These are as likely to be concerns of men as they are of women. Thus, contrary to Horner's (1972, 1974) theory, sex role socialization is not sufficient to explain the development of this form of FOS. The real developmental factors that cause some people, male or female, to score high on Factor 1 remain to be identified.

We should not ignore the possibility that Horner was correct about the link between femininity and FOS in 1968. (Her data were collected in 1965.) The social climate has changed considerably since then, and this certainly could have affected our subjects, who were college juniors and seniors in 1976. In fact, Tresemer (1976) presented evidence for a historical change. Despite changes in sex role orientation, and perhaps also in atti-

tudes toward achievement, however, we still find many males and females who experience FOS as measured by Factor 1.

The factor closest to Horner's (1969b) original measure of FOS is Factor 4, which we have called Attitudes Toward Success in Medical School to indicate that we doubt whether it has much to do with fear of success. In our study, as in Spence's (1974), males were actually more negative toward a successful male medical student than females were toward a corresponding female. Spence showed that the reasons for the hostility were not identical for males and females. Thus, some of Horner's arguments might be correct despite what seems to be a strongly contradictory pattern of results. However, given that the attitudes expressed in people's stories are quite complex and probably specific to the medical school situation, it is not surprising that research based on this measure has been confusing and contradictory (Tresemer, 1976).

Factor 5, Extrinsic Motivation to Excel, was not anticipated and remains somewhat of a mystery. For the moment, the most important point to be made about Factor 5 is that it contains items from the scales designed by Pappo (1973) and Zuckerman and Allison (1976), who expected the items to indicate absence of FOS; in fact, they appear to measure an entirely different dimension.

Directions for further research are clear. (a) It would be useful to develop shorter scales to represent Factors 1, 2, and 5. Spence's measure and the existing test anxiety scales are acceptable in their original forms. (b) Experimental studies are needed to assess the behavioral consequences of FOS and fear of failure. FOS could be measured by the items on Factor 1; either Factor 2 or Factor 3 could be used to measure fear of failure, whichever proves to have the most construct validity. Presumably, a person for whom FOS is the dominant motive would perform more poorly following success than following failure. A person with strong fear of failure and little or no fear of success should be disorganized by failure but quite pleased by success. (c) The possibility that achievement conflicts lead to psychosomatic symptoms of specific kinds deserves much

more attention than it has received to date. (d) It is important to determine the developmental antecedents of the kind of FOS measured by Factor 1. (e) Since we did not include Horner's most recent measure (Horner et al., Note 1), it would be useful to conduct a study explicitly to determine how her new measure, which is beginning to be widely used, is related to the five dimensions discussed here. If Jackaway and Teevan (1976) are right, Horner's new measure will be substantially correlated with our fear of failure dimensions (Factors 2 and 3). (f) Finally, it is important to reevaluate Atkinson's model of achievement motivation (Atkinson & Feather, 1966) in light of FOS research. Horner intended for the concept to play a role in a revised comprehensive model of achievement behavior, but so far no one has proposed such a model.

WISC-R Factor Structures Among Anglos, Blacks, Chicanos, and Native-American Papagos

Daniel J. Reschly
Iowa State University

Wechsler Intelligence Scale for Children-Revised (WISC-R) factor structures were compared for sample of Anglo, Black, Chicano, and Native-American Papago children from Pima County, Arizona. The samples were randomly selected from school enrollment rosters and stratified by ethnicity, grade level, sex, and urban-rural residence ($N = 950$). Application of two objective procedures for determining the appropriate number of factors for each group suggested a three-factor solution for Anglos, a two- or three-factor solution for Chicanos depending on procedure used, and two-factor solutions for Blacks and Native-American Papagos. The two-factor solutions were highly similar for the four groups. The three-factor solutions were similar for Anglos and Chicanos but were substantially different for the other groups. The groups were highly similar in terms of the proportion of variance accounted for by a general factor, and the Verbal-Performance scale distinction appeared equally appropriate for all groups.

Examination of the construct validity of a test in samples of diverse sociocultural groups provides evidence concerning the appropriateness and fairness of the use of the test with different groups. Comparability of factor analysis results for different groups, and the degree to which the results of the factor analysis are consistent with the major scores and common interpretations of the test are necessary conditions for fairness in use of the test with culturally diverse persons. Indeed, if a test is not measuring the same underlying abilities or if the commonly used scores from the test represent varying abilities depending on group membership, then use of the test with culturally different persons is probably

inappropriate and unfair, and the predictive validity of the test is likely to be lower for specific groups. Since the Wechsler Intelligence Scale for Children (WISC) and the Wechsler Intelligence Scale for Children-Revised (WISC-R) have been the most frequently used measures of general intelligence in schools and clinics, data from diverse groups concerning the construct validity of the WISC-R are needed for practitioners to make judgments concerning its appropriateness and possible fairness.

Although numerous investigations of the factor structure of the WISC appeared in the literature (Sattler, 1974), only three studies compared factor similarity among diverse sociocultural groups, and no studies on the WISC-R of this nature have appeared to date. Generally, these studies found high similarity for Blacks and Anglos (Lindsey, 1967) and for Blacks, Anglos, and Chicanos (Silverstein, 1973) when two-factor solutions for the WISC-R were used. However, when the three-factor solutions were applied (Semler & Iscoe, 1966), significant differences resulted in the second and third factors for Blacks and Anglos.

The collection of these data was supported by a grant from the Arizona State Department of Education, Division of Special Education, through Title VI-B, EHA (91-230) funds. The technical assistance provided by Larry Hanser in the analysis of the data and the cooperation and assistance of the school districts, state department personnel Karen Davis, Earl Pike, and Fred Jipson in the collection of the data are gratefully acknowledged.

Requests for reprints should be sent to Daniel J. Reschly, Department of Psychology, Iowa State University, Ames, Iowa 50011.

The present study attempted to extend Kaufman's (1975) factor analysis of the 1974 WISC-R to three non-Anglo groups. Kaufman interpreted three factors in an analysis of the standardization data by age level. These factors were labeled *Verbal Comprehension* (VC), formed by the subtests of Information (I), Similarities (S), Vocabulary (V), and Comprehension (C); *Perceptual Organization* (PO), formed by Picture Completion (PC), Picture Arrangement (PA), Block Design (BD), Object Assembly (OA), and Mazes (M); and *Freedom from Distractibility* (FD), formed by Arithmetic (A), Digit Span (DS), and Coding (Co). In addition, strong support from the factor analysis data was reported for Wechsler's use of the Full Scale IQ score as an index of general intelligence and for the organization of the test into the Verbal and Performance IQ Scales. Silverstein (1977) also factor analyzed the standardization data, and, although a slightly different method of rotating factors was used, the same three-factor pattern emerged. Thus, the WISC-R factor structure, in contrast to the WISC, appears to be highly stable across both age levels and different methods of conducting the analysis.

The purposes of the present study were to examine the appropriateness and fairness of the WISC-R for four sociocultural groups in terms of (a) comparability of factor structures; that is, does the WISC-R measure the same underlying abilities for Anglo and non-Anglo groups? and (b) construct validity evidence for the Full Scale IQ and the verbal-performance organization of the test; that is, does the Full Scale IQ measure general intelligence and do the Verbal and Performance IQ scores represent somewhat different but overlapping abilities for the four groups?

Method

Sample

In November 1973 the Division of Special Education, Arizona State Department of Education funded a comprehensive study of handicapping conditions among school-age children. The Pima County Special Services Cooperative was authorized to conduct the study in Pima County. The data reported herein were gathered as part of this study. Pima

County is geographically large (9,200 square miles), ethnically diverse (approximately 68% Anglo, 25% Chicano, 4% Black, and 3% Native American), and largely urban in population (Tucson) with extensive and sparsely populated rural areas.

A stratified random sample of 1,040 children was selected with equal numbers from each of the stratification variables of group (Anglo, Black, Chicano, and Native-American Papago, $n = 260$ per group), sex, urban-rural residence, and grade (first, third, fifth, seventh, and ninth; $n = 208$ per grade). The entire sample of Black children was urban, and the entire sample of Native-American Papago children was rural due to the very low proportions of urban Indians and rural Blacks in Pima County.

The cooperation of Tucson District 1, which enrolls about two thirds of all school-age children in the county, and all of the rural school districts in the county was obtained through contacts with district authorities. School district enrollment rosters were used to randomly select the sample. Ethnicity was determined by school data and in some cases by contacting the parents. Tucson District 1 was regarded as urban. Outlying districts, 25 miles or more from Tucson, were regarded as rural. Parents of children selected in the initial sample were contacted by letter or phone to explain the nature of the study and to solicit written permission. If parent permission was not obtained due to refusal (4%), no reply (18%), or the child withdrew from school, parents moved, and so forth (11%), another child was selected from an alternative sample constituted by the above process. There were no appreciable differences among the groups in percentages of parents granting permission, refusing permission, no reply, or no address—family moved, and so forth. Due to various logistical problems, for example, delays in return of parental permission, school scheduling problems, and availability of examiners to travel to remote areas, WISC-R scores were obtained for 950 of the original sample of 1,040 students (Anglo, $n = 252$; Black, $n = 235$; Mexican American, $n = 223$; and Native-American Papago, $n = 240$). The average age of the final sample was 10.63 years (range from 6.28 to 15.87 years) including 468 males and 482 females. Additional information concerning the sample is provided in Reschly and Jipson (1976).

As soon as parental permission was obtained, appointments were made with school officials to administer the various assessment procedures. The WISC-R was administered by appropriately trained examiners, and all WISC-R protocols were further checked by me for clerical and scoring errors.

Analysis

For each of the four ethnic groups, two procedures were used to provide a guide to the appropriate number of factors needed to efficiently and thoroughly describe the WISC-R. Following Silverstein's (1977) and Kaufman's (1975) methods, a principal components analysis was conducted with

is in diagonals. An eigenvalue greater than 1 was the criterion for determining the appropriate number of factors. Second, an unrestricted maximum likelihood analysis was conducted for the two-, three-, and four-factor solutions. At each step in the analysis, a chi-square goodness of fit test was conducted to compare the resulting factor matrix and the original correlational matrix.

A principal factor analysis with squared multiple correlations in the diagonals was then conducted separately for each group followed by varimax rotation of the two-, three-, and four-factor solutions. Varimax rotation of the two-, three-, and four-factor solutions was conducted regardless of the outcomes of the tests for appropriate number of factors to conform as closely as possible to the previous literature.

Results

Number of Factors

The techniques used as guides to the appropriate number of factors yielded somewhat inconsistent results. The principal components criterion (eigenvalues > 1) suggested three-factor solutions for Anglos and Chicanos and two-factor solutions for Blacks and Native-American Papagos. The chi-square tests for goodness of fit of the two-factor solutions, that is, testing the hypothesis that the resulting two-factor matrix accounts for the variation in the original matrix of simple correlations among subtests, suggested that more than two factors were required only for Anglos ($p < .07$) and that two factors were sufficient for the other groups ($p > .15$). Using Kaufman's (1975) reasoning, a three-factor solution might be explored for all of the groups, since there was evidence for the insufficiency of a two-factor solution for some of the groups, and the eigenvalues for the third factor in the three-factor solutions were very close to 1.0 for all groups. Although the ultimate criterion for the appropriate number of factors is psychological meaningfulness (including descriptive efficiency, statistical invariance, and predictive utility), the objective guides clearly suggested only two factors for Blacks and Native Americans and perhaps only two factors for Chicanos.

Comparison of Two-Factor Solutions

The two-factor solutions yielded the now familiar pattern of a first factor composed

of the Verbal scale subtests and a second factor constituted by the Performance scale subtests.¹ The subtests with the highest loadings on the first factor for all groups were Vocabulary (V), Information (I), Comprehension (C), and Similarities (S), although all the verbal subtests were significantly related to the first factor. (Loadings were .40 or above for all six subtests except for the loading of Digit Span (DS) for one group, $Mdn = .65$.) The second factor formed by Performance scale subtests was again highly similar across the four ethnic groups. The Block Design (BD) and Object Assembly subtests had the highest loadings for all groups. All Performance scale subtests were significantly related to the second factor (loadings of .40 or above) except for Coding (Co), which was not a significant component of the second factor for any of the groups (loading $< .30$ for all groups). Examination of coefficients of congruence between matching factors among the four groups further supported the judgment of very high similarity among the factors. The 12 coefficients of congruence varied from .97 to .99.

Comparison of Three-Factor Solutions

Three- and four-factor solutions were analyzed for all groups even though the objective criteria unequivocally supported three factors for Anglos only, either two or three factors for Chicanos depending on the criterion used, and only two factors for Blacks and Native-American Papagos. In addition to inspection of the size and pattern of the loadings on the factors, coefficients of congruence were computed among matching factors for the groups in this study and between the varimax median loadings reported for the standardization sample (Kaufman, 1975, Table 4, p. 141). The three-factor solution for Anglos (see Table 1) was virtually identical to the three-factor pattern reported for the standardization sample

¹ Tables of the subtest loadings for each group in the two-factor solutions and the coefficients of congruence for matching factors in the two- and three-factor solutions are available from the author. Also, the loadings of each subtest on the first unrotated factor are available in these tables.

Table 1

Wechsler Intelligence Scale for Children-Revised Subtest Loadings in Three-Factor Solution for Four Ethnic Groups

Subtest	Anglo			Black			Chicano			Native-American Papago		
	I	II	III	I	II	III	I	II	III	I	II	III
Information	63	32	26	66	40	18	66	20	33	68	22	21
Similarities	59	26	26	59	41	13	67	15	22	58	33	11
Arithmetic	43	26	45	61	34	27	40	13	45	42	37	09
Vocabulary	74	23	12	75	20	16	67	26	30	74	15	05
Comprehension	64	22	21	71	24	09	61	20	06	70	10	17
Digit Span	35	02	40	49	08	36	33	14	31	30	35	09
Picture Completion	20	49	09	25	52	21	32	52	12	21	53	14
Picture Arrangement	20	53	00	29	53	24	17	38	39	23	44	03
Block Design	17	60	22	20	33	58	20	59	16	14	69	05
Object Assembly	07	59	18	10	17	58	14	58	09	07	51	25
Coding	12	16	40	33	20	22	14	16	37	17	17	37
Mazes	18	42	10	23	44	30	06	47	20	14	51	28

Note. All decimal points have been omitted. Roman numerals refer to the factor number: Factor I = Verbal Comprehension; Factor II = Perceptual Organization; Factor III = Freedom from Distractibility.

by Kaufman (1975). The first factor was formed by the V, C, I, and S subtests. The A and DS subtests also had substantial loadings on the first factor, but their highest loadings were on the third factor. The second factor for Anglos was the familiar Perceptual Organization (PO) factor formed by the BD, OA, Picture Arrangement (PA), Picture Completion (PC), and Mazes (M) subtests. A third factor, previously described as Freedom From Distractibility (or memory, number, sequential, etc.) was formed by the A, DS, and Co subtests. Coefficients of congruence between the three-factor solutions for Anglos and the data reported by Kaufman were .98, .98, and .97, respectively, for the three factors, further supporting the conclusion of near-perfect replication of the three-factor patterns reported for the standardization sample.

The first two factors in the three-factor solution for Chicanos were highly similar to the above pattern, but the third factor was slightly different in that the loading on PA was slightly higher on the third rather than the second factor, and the loading of DS on the third factor was somewhat lower. Coefficients of congruence for the three factors, respectively, between the Chicano and Anglo loadings were .99, .98, and .86, and .98, .99, and .93 between the loadings for Chicanos and the standardization sample.

The three-factor solutions for Native-American Papagos and Blacks were clearly different from the previously reported three-factor solutions and should, perhaps, *not* be interpreted at all, since the objective guides to appropriate number of factors suggested the sufficiency of two-factor solutions. For both groups, the first two factors in the three-factor solutions were formed by the Verbal and Performance scale subtests, respectively. However, for Blacks the second factor was formed by PA, PC, and M and the third factor by BD and OA. Thus the third factor for Blacks appeared to involve a splitting of the second factor into two factors and clearly did not match the previously reported patterns for the third factor. A similar result was obtained for Native-American Papagos for whom the third factor was formed by one subtest only (Co), which suggests subtest-specific or method variance rather than a factor as such. However, it should be noted that the third factor for Native-American Papagos was similar to what Cohen (1959) called Factor E (Quasi-Specific), which also was formed primarily by Co. Coefficients of congruence for the three-factor solutions among all groups and the standardization data were very high for the first factor ($\geq .96$) and only slightly lower for the second factor ($\geq .89$). However, for the third factor, the coefficients for Blacks

and Native-American Papagos were significantly lower (.72-.78) in all comparisons, further supporting the conclusion of *not* interpreting a third factor for these groups.

The fourth factor in the four-factor solutions was uninterpretable for all groups. (All subtest loadings were $<.30$ with most near zero on the fourth factor.)

General Intelligence

The data were further analyzed to determine the degree to which a general factor of intelligence was measured by the WISC-R for the different groups. In addition to the obvious evidence of a general factor, that is, the significant and positive correlations of subtests with each other and with Full Scale score, three indices of a possible general factor were examined. First, following Kaufman's (1975) analysis, which resulted in a median of 82% of the common factor variance attributed to the general factor, the loadings on the unrotated first principal factor were analyzed separately for each group. The percentage of common factor variance accounted for by the general factor was nearly the same regardless of group (79, 83, 79, and 77, respectively, for Anglos, Blacks, Chicanos, and Native-American Papagos). A second analysis of the general factor using the first unrotated principal component resulted in about the same percentages for each group.

A third index, which I preferred, was based on a restricted maximum likelihood analysis that used a target matrix based on the results of the two-factor solutions for each group. This method provided a lower but more realistic estimate of the variance attributable to the general factor, because the unique variance associated with the Verbal Comprehension (VC) and PO factors (clearly the strongest factors for all groups) was taken from the general factor and apportioned to the respective VC and PO factors. This analysis yielded estimates of 61%, 63%, 59%, and 61% of the variance attributable to a general factor for Anglos, Blacks, Chicanos, and Native-American Papagos, respectively. Regardless of the index used, the proportions of variance attributable to a general factor were approxi-

mately the same for all groups and similar to the standardization sample.

Verbal-Performance Organization

The first and second factors, VC and PO, were highly similar to the respective Verbal and Performance scales in the two-factor solutions for all groups and in the three-factor solutions for all groups except Blacks. The closeness of the VC and PO factors to the verbal-performance dichotomy is even greater when the supplementary subtest for the verbal scale (DS) is ignored and when M is substituted for Co on the Performance scale. If these stipulations are followed, then the respective scales conform almost perfectly to the first and second factors for all groups.

Discussion

Some caution regarding the results of this study must be expressed, since in addition to race or ethnicity, the groups also varied significantly on socioeconomic status and level of intelligence. Due to limitations in sample size in this and most other investigations, it was impossible to analyze separately the possible effects of socioeconomic status, level of intelligence, and group membership. The well-known fact that these variables are not independent requires caution in interpreting the *differences* reported among the groups. A slight relationship between level of intelligence and factor patterns on the WISC and WISC-R has been reported previously (Van Hagen & Kaufman, 1975), and may partially account for the group differences reported here.

The major differences in factor patterns among the groups were essentially restricted to the question of the existence and composition of the third (Freedom from Distractibility—FD) factor. The number of interpretable factors on the WISC-R varied for these samples, and perhaps vary for these groups generally. The previously reported pattern of three factors for Anglos was clearly replicated, and the results for Chicanos were generally consistent with this pattern. However, the objective guides to the appropriate number of factors and the pattern of factor load-

ings in the three-factor solutions both failed to support the existence of the third (FD) factor for Blacks and Native-American Papagos. The existence of the third factor on the WISC was the subject of some debate (Silverstein, 1969), and the "meaning" of this factor has never been altogether clear. Some researchers (e.g., Cohen, 1957) regard the third factor as a measure of intellectual skills such as immediate memory, numerical or sequencing. Others, including Cohen (1959), have described the third factor in more behavioral or nonintellectual terms such as attention-concentration, or more commonly now, Freedom from Distractibility (Kaufman, 1975). If the third factor is viewed as a non-intellectual factor, then the construct validity of the WISC-R as an *intellectual* measure for different groups is supported even more strongly by these data.

Interpretation of the factor scores of VC and PO appears to be equally appropriate for all of the groups included in this study. Following Kaufman (1975), the Verbal Scale IQ can be used for the VC factor, and if M is substituted for Co, the Performance IQ can be used as for the PO factor. However, the FD factor for Chicanos should probably involve four subtests (adding PA to the usual three), and the FD factor scores should probably *not* be used with Blacks and Native-American Papagos unless other data suggest its existence and/or predictive utility for these groups.

Confidence in the appropriateness of the WISC-R as a measure of intellectual ability for different groups is increased by the fact that (a) a large general factor was clearly apparent in about the same form and amount for all groups. Thus, the usual interpretation of the Full Scale IQ as an index of general intelligence appears to be equally appropriate for Anglo and non-Anglo groups. Further, the Verbal-Performance scale distinction appears also to be equally appropriate for the four groups.

Finally, the conclusions of this study provide increased confidence in the construct validity of the WISC-R for different groups. Construct validity evidence is certainly a *necessary* but not a sufficient condition for fairness in test use. These conclusions, of course, do not reveal whether or not the common predictions and classifications based on the WISC-R are equally valid for diverse sociocultural groups.

General Versus Specific Traits in the Assessment of Anxiety

Martin Mellstrom, Jr., Marvin Zuckerman, and George A. Cicala
University of Delaware

The study compared the predictive validity of anxiety measures based on the general trait approach and approaches that include the situation dimension in the test. The subjects were 56 male and 58 female undergraduates. The subjects were pretested with general and specific trait anxiety measures and were later exposed to three situations involving a rat, a test, and social anxiety. The results indicated that the predictive validity of the specific measures was significantly greater than that of the general measures in 7 of 32 comparisons, whereas the reverse never occurred. Other analyses showed some support for the presence of behavioral consistency; for example, the generalizability coefficient for persons across situations and response modes was about .35, but little support was found for the traditional general trait tests that purport to measure them.

During the past decade there has been considerable debate in the field of personality and assessment on the relative importance of traits and situations. The traditional "trait" approach, which calls attention to enduring intrapsychic dispositions and deemphasizes the role of the environment, has been attacked on both theoretical and empirical grounds, and alternative models have been proposed. The behavioral or "situationist" approach (e.g., Kanfer & Saslow, 1965; Mischel, 1968), which has been one of the most widely accepted of these alternatives, can be characterized by an emphasis on the role of the current environment or situation in determining behavior. More recently, proponents of the interactional approach have suggested that neither trait nor situationist accounts of behavior are adequate, and that

the person and the situation must be considered in their interaction to provide an adequate conceptualization of behavior (cf. Bowers, 1973; Ekehammar, 1974; Endler & Magnusson, 1976).

Although reviews of the evidence on which of these approaches holds the most promise as a model for the study of personality (e.g., Bowers, 1973; Ekehammar, 1974; Endler & Magnusson, 1976) seem to support some form of interactional approach, it is not yet clear that an application of this approach to assessment problems will yield gains in our ability to understand and predict behavior. Studies of the problem in the area of anxiety (e.g., D'Zurilla, 1965; Hodges & Spielberger, 1966; Lamb, 1973; Mellstrom, Cicala, & Zuckerman, 1976; Paul, 1966) have compared the predictive validity of "anxiety trait" (A-Trait) tests that included the situation variable in the design of the test with those that did not. In these studies, "general A-Trait" tests, like that of Spielberger, Gorsuch, and Lushene (1970), which are intended to measure relatively stable individual differences in general anxiety proneness, are evaluated against "specific A-Trait" measures, which assess a person's disposition to be anxious in a particular situation or class of situations, for example, classroom examination situations. The idea of specific traits can be viewed

This article is based on a dissertation submitted by the first author in partial fulfillment of the requirements for the PhD degree from the University of Delaware. The authors would like to thank the following students for their work as experimenters in the present study: John Baltadonis, John Cavanaugh, Pamela Gravatt, Sandra Herman, George Laskaris, Frank Shields III, and Nancy Trump.

Martin Mellstrom, Jr., is now at the Psychology Service, Veterans Hospital, Lyons, New Jersey 07939. Requests for reprints should be sent to Marvin Zuckerman, Department of Psychology, University of Delaware, Newark, Delaware 19711.

as a redefinition of the trait concept so that it takes into account the situation and the Person \times Situation interaction.

Although the results, on the whole, have indicated that specific A-Trait measures are more predictive of anxiety in the corresponding criterion situation, there have been instances in which the general A-Trait tests were nearly or equally as predictive. This has seemed to happen when there was some threat to self-esteem ("ego threat") in the criterion situation (Mellstrom et al., 1976). Thus, the issue of whether anxiety assessment procedures based on a general trait model of personality are inferior to those that introduce the situation variable into assessment has been unresolved because the variable of ego threat has not been adequately explored and only a small number of anxiety situations have been evaluated. The present study attempted to help clarify this issue by having individuals who were pretested with general and specific A-Trait tests experience three anxiety situations, two of which posed a clear ego threat (social and test anxiety situations) and one of which did not (a rat situation).

Method

Subjects

Fifty-six male and 58 female students enrolled in introductory psychology at the University of Delaware were selected for the study. They participated to fulfill a course requirement.

Predictor Tests

Since all the predictors have been described in the Mellstrom et al. (1976) study, they will be only briefly described here.

Two of the pretests can be regarded as traditional A-Trait measures: (a) The trait form of the State-Trait Anxiety Inventory (STAI A-Trait; Spielberger et al., 1970) measures individual differences in anxiety proneness and has been found to correlate .73 with the Neuroticism scale of the Eysenck and Eysenck (1964) Personality Inventory (Mellstrom et al., 1976); (b) the Neuroticism (N) scale of the Eysenck Personality Inventory (EPI) was the second general anxiety measure used.

Two pretests provided indices of both general and specific A-Trait: (a) The Geer (1965) Fear Survey Schedule (FSS) consists of self-rated fear reactions to 51 commonly feared objects and situations. Subjects' total fear scores across all 51 items were used

as a general fearfulness or A-Trait measure, and their scores on the particular items were used as specific A-Trait measures. (b) Another test that provides indices of both general and specific A-Trait is a modified form of the Zuckerman Inventory of Personal Reactions (ZIPERS; Zuckerman, 1976, 1977). It consists of 12 situations in which subjects indicate the degree to which each situation elicits in them each of 13 reactions. Factor analysis of the response dimensions of the scale has yielded several factors including the fear arousal factor used in the present research. By summing a subject's scores across all situations on the responses comprising the fear factor, a measure of general A-Trait can be derived. A subject's score in response to any one of the 12 situations yields a specific A-Trait measure. The test was modified by adding social, test, and rat situations, which matched the real situations in the study, to the usual form of the test. Responses to these situations were not included in subjects' total scores, which were obtained by summing responses across the other situations.

Anxiety Situations

Rat. In the rat situation, an albino laboratory rat with clipped front incisors was housed in a wire cage located on a table in the corner of the 4 m square \times 3.5 m high experimental room.

Test. The test situation was similar to that used by Sarason (1957) to study test anxiety and involved a memory drum used to provide a serial verbal learning task. Ten nonsense syllables were presented at the rate of one every 1 sec, and the subject's task was to say when a given syllable appeared what the next one to appear would be. According to Sarason, when subjects are told that this task is a measure of intelligence, the resulting evaluation anxiety disrupts the performance of those who are "test anxious." Subjects spoke into a tape recorder connected to an audio oscillator so that a "beep" (inaudible to the subject) was recorded on the tape each time a new word was presented on the memory drum. Using this arrangement, subjects could be left alone to perform the task, and their tape can be scored later for the number of trials required to learn the list. Thus, anxiety in this situation would not be contaminated by social anxiety related to the presence of other people.

Social situation. This situation consisted of a non-directive interview during which subjects were asked to "talk about themselves" for 2 minutes. The first author conducted the interview while he and two other experimenters, one male and one female, gazed directly and continuously at the subject. This procedure was followed because of Marks's (1969) observation that one of the cardinal features of social anxiousness is a fear of the gaze of others. Although it never occurred, experimenters were instructed to stop gazing if it appeared that the subject was becoming very distressed by it. A videotape camera, focused on the subject, was also located in the room, but subjects were given no indication of whether it

was operating until the end of the experimental session. The situation could be observed from an adjoining room, where the videotape deck was located, through a one-way mirror.

Subjective Situational Anxiety Measures

The three tests used to measure subjective anxiety in each situation were the Anxiety State (A-State) scale of Spielberger et al.'s (1970) STAI; the A-State form of the ZIPERS, which consists of the items of the 13 reactions on the ZIPERS, with instructions to indicate the reactions being experienced "now"; and the fear thermometer (FT) of Walk (1956), in which subjects place a check mark on a 1-10 scale to indicate the amount of fear or anxiety being experienced at that moment.

Subjects were administered the predictor tests during the first 4 weeks of the semester. Six weeks later, each subject participated in each anxiety situation once, with the temporal order of the situations determined randomly for each subject. To minimize carryover effects from one situation to the next, subjects were scheduled for no more than one situation on a given day.

Rat Situation Procedure

Taped instructions directed the subject to approach the rat and lift it up. In this, as in the other two situations, subjects were told that they did not have to participate if they did not wish to, but no subject chose this option. Following the instructions, subjects were administered the first two A-State scales (STAI A-State and ZIPERS-State). While they completed these scales, the experimenter rated them on a modified form of Paul's (1966) Behavior Checklist in which the experimenter rates the degree to which each of the checklist behaviors is noticeable. An extra item of "overall anxiety" was added to the checklist.

The behavioral test was identical to the one used in the Mellstrom et al. (1976) snake situation and is basically a behavior approach test, yielding a "task score" and a latency measure as the behavioral fear indices. After this task was completed, the subject filled out a FT as he or she stood in the location of the closest approach to the rat. In all three situations, subjects were told that they did well relative to others to prevent possible loss of self-esteem.

Test Situation Procedure

Taped instructions told subjects that they would be asked to perform a difficult memory task that is an indicator of one's intelligence. Then the first two A-State scales were completed while the experimenter filled out the Behavior Checklist. Next, the memory task was begun, and the experimenter left the room. At the end of 15 minutes, he or she returned, terminated the task, and administered the FT.

Social Situation Procedure

Taped instructions asked subjects to talk about themselves for 2 minutes. The first two A-State scales were then administered, the "interview" was conducted, and the FT was completed. Before subjects left, they were told that they had been videotaped but that if they objected, the tapes would be erased. No subjects requested this. After subjects left, the experimenters watched the tape of the interview and completed the Behavior Checklist. The videotapes provided additional behavior ratings made by a separate set of observers, but these ratings were uncorrelated with the other measures in the study, so they will not be reported.

Results

Before the main results are discussed, it should be noted that there was a truncation of range in the behavioral measure of the rat situation (task score), since only 6 males and 15 females could not perform the task. As a consequence, the correlations of this variable with the predictors were expected to be somewhat low.

Comparative Validity of the General and Specific Predictors

In the previous study (Mellstrom et al., 1976), the correlations among the predictor measures indicated three fairly distinct

Table 1
Intercorrelations Among the Three Classes of Predictor Measures

Scale	Omnibus	Neuroticism	A-Trait	
			Rat	Test
Neuroticism	.49

classes: neuroticism, omnibus, and specific A-Trait measures as represented by measures like the EPI-N, total score on the FSS, and a single item on the FSS, respectively. Measures within a given class were found to correlate more highly with each other than with other measures, and to show very similar patterns of correlation with the situational criteria. Therefore, to simplify interpretation of the data, tests comprising one class were combined to form one composite measure by summing subjects' standard scores on each test. For example, subjects' standard scores on the STAI A-Trait and EPI-N scales were summed to provide a composite labeled *neuroticism*. An additional justification for this procedure is that the focus of the study was not on the validity of any single test, which may be affected by the amount of effort put into its construction, but on the validity of different strategies of assessment as represented by more than one measure.

The response data of the present study were prepared for analysis in the same way. On the basis of an a priori decision, based on the foregoing theoretical rationale, sub-

jects' standardized total scores on the FSS and ZIPERS were summed to provide a composite labeled *omnibus*. The STAI A-Trait and EPI-N scales were combined to form a neuroticism composite, and the specific A-Trait measures derived from the ZIPERS and FSS were similarly combined for each specific disposition, yielding specific composites for "social anxiety," "test anxiety," and "rat anxiety."

As in the prior study, situational criteria of the same type were combined to form self-report, observers' rating, and behavioral index composites. STAI A-State, ZIPERS-State, and the FT comprised the "self-report" composite, total score on the Behavior Checklist and the additional "overall anxiety" item comprised the "observers' rating" composite, and, in the rat situation, the task score and latency formed a "behavioral index" composite.¹

¹ Anyone interested in the correlations between the single predictor measures and the separate fear response measures can obtain a table of these correlations from the second author.

Table 1 shows the correlations among the composite measures representing the several classes of predictors for the entire sample of subjects. The omnibus composite showed moderate to strong correlations, ranging from .49 to .80 with all the other predictors, whereas the neuroticism composite showed somewhat weaker but significant correlations. The specific A-Trait composites for test and social anxiety correlated highly (.65) and were more highly related to the neuroticism composite than was the rat A-Trait composite.

Tables 2 and 3 show the correlations between the three classes of predictors and the situational fear measures for the male and female samples, respectively. The validity coefficients of the specific compositions represent the relations between the situational anxiety measures and the specific composite designed to predict that anxiety. To compare the validity coefficients of the three types of A-Trait predictors, a *t* test for the significance of the difference between two correlation coefficients in correlated samples (Ferguson, 1971) was used. The right-hand por-

tion of the tables shows the results of these comparisons.

For the rat situation, there were several instances in which the specific composite had significantly more accuracy in the prediction of criteria than either the omnibus or neuroticism composites. Also, the specific composite correlated significantly with all three types of situational measures except the behavioral criterion for the males, which was limited by range restriction, whereas the neuroticism composite correlated significantly with self-reports and observer's ratings but not with behavioral measures.

In the test situation, there was little or no evidence of differential predictive power for the three types of predictors. For the females in the social situation (Table 3), the specific measure was significantly better than the omnibus one in predicting both types of situational responses. Overall, the specific measures were significantly more predictive in 7 of 32 comparisons, whereas the reverse never occurred; that is, the general measures were never significantly more predictive. Also, the

percentages of significant ($p < .01$) correlations for the omnibus, neuroticism, and specific predictors (Tables 2 and 3) were 38%, 38%, and 50%, respectively, for the males and 25%, 38%, and 75% for the females. The results suggest that the specific predictors had somewhat greater overall predictive accuracy than the other two types of A-Trait measures.

Proportions of Variance: Persons Versus Situations

To assess the relative importance of persons, situations, and their interaction, the ZIPERS data were subjected to three-way analyses of variance. In the first analysis, each subject represented a level of the person source, whereas the social, test, and rat situations described in the inventory represented levels of the situation source. The three response items that represented the mode of response source were "Your heart beats faster," "You feel fearful," and "You get out of the situation or avoid it." The rationale for using these three responses was that each represents one of the three basic human response channels: physiological, phenomenal, and behavioral. Also, it was thought preferable to have the same number of response modes as situations.

After the analyses of variance were performed, the proportions of variance explained

Table 4
Percentages of Variance Accounted for by Sources, with Individuals Comprising Levels of the Person Source

Source	Type of situation	
	Hypo- thetical	Actual
Person (P)	35.2	29.0
Situation (S)	.0	.6
Response mode (R)	4.6	5.7
P \times S	14.0	21.5
P \times R	16.8	11.7
S \times R	2.5	.7
Residual	26.8	30.8

Note. The hypothetical situations were the rat, test, and social situations described in the Zuckerman Inventory of Personal Reactions. The actual situations were those actually experienced by subjects in the study.

by each source were calculated, following guidelines described by Endler (1966). The proportions were calculated twice under a mixed model (persons random, situations, and response modes fixed), once assuming a minimum and once a maximum triple interaction. Since the two sets of results were quite similar, it was possible to make the assumption of a zero triple interaction, permitting a unique solution for each component.

Regarding statistical significance, this $n = 1$ model permits F tests on only the situation and response mode main effects and the Situation \times Response Mode interaction effect. Of these three, only the situation effect was not significant in either the hypothetical or actual situation data sets.

Table 4 shows that the person source accounted for 35% and 29% of the variance in the responses to the hypothetical and actual situations, respectively. In contrast, situations accounted for only 0%–1%, a finding related to the fact that the means of the three situations were nearly identical. Mode of response explained only 5%–6% of the responses to the hypothetical and actual situations, and

the Person \times Situation interaction accounted for 14% or 22%, depending on the data set. The residual accounted for 27% or 31%, depending on the data set. Females had significantly higher anxiety levels than the males on the ZIPERS specific A-Trait predictors, but they did not differ from males on any of the A-State responses in the actual situations.

To assess the importance of individual differences when defined by traditional general A-Trait tests, more analyses of variance were performed on the ZIPERS data when the person source was represented by groups of subjects scoring high, medium, and low on the neuroticism composite. The situation and response sources were the same as before, and the analysis was done on both the hypothetical and actual situation data sets.

The results of this change were that the A-Trait or neuroticism source explained only 12% and 9% for the hypothetical and actual situation data sets, respectively. As before, situation explained little or no variance, but in this analysis the error term accounted for 69%–81% of the variance.

Individual Consistency Across Situations

As pointed out by Endler and Magnusson (1976), one of the main postulates of the trait position is that the rank ordering of individuals on a given trait should remain the same from situation to situation. To determine the validity of this postulate for the data of the present study, the correlations of a given situational anxiety measure with the same measure taken in other situations were examined. Table 5 shows that the size of the correlations varied considerably from measure to measure, ranging from .16 to .51, with the median correlation at about .36.

Another index of consistency, the generalizability coefficient (Cronbach, Gleser, Nanda, & Rajaratnam, 1972), was computed on the ZIPERS data and submitted to analysis of variance. The person source had the largest coefficients, .38 and .31, respectively, for the hypothetical and actual situations, whereas the situation source had coefficients near zero, demonstrating no consistent or generalizable effect across persons.

Discussion

The findings on the comparative validity of the general and specific A-Trait measures corroborate those of the earlier study (Mellstrom et al., 1976) and suggest that the specific measures may be more useful for prediction of fear responses. The specific composites surpassed the general ones in the rat situation for both sexes and in the social situation for females. In both of these instances, it would seem that subjects were capable of imagining how they would respond in the situation, and that this estimate was more accurate than one based on a measure of the person's general anxiousness.

Instances in which the general tests equaled the predictive accuracy of the specific ones (i.e., in the social situation for the males and in the test situation for both sexes) can be explained in several ways. First, the predictive power of the specific predictors may have been limited by two factors: (a) Subjects probably had no prior experience with anything similar to the test situation of the study, making it difficult for them to predict on the ZIPERS how they would react. and (b) There was a lack of correspondence between the test "situation" described in the FSS test item and the actual situation confronted; that is, performing a serial verbal learning task in an experiment differs considerably from "failing a test," the situation described in the FSS test item. Second, the specific predictors did not surpass the general ones in predicting the self-report criteria of the test situation, because the general ones achieved relatively high levels of predictive accuracy for this situation. It may be that the ego threat present in such situations is the main cause of anxiety, permitting the neuroticism composite to be predictive of these self-reports. Third, the general and specific predictors may have shown equal predictive validity for the males in the social situation because many males may be less likely than females to accurately imagine their responding in social situations. That is, in line with traditional sex roles, females may be more attentive to subtle social cues and to their own responding in such situations.

Thus, while the idea of including the situa-

tion variable in assessment seems to be theoretically sound and often yields increments in predictive validity, variables like the "ego involvement" of subjects, their prior experience (or lack of it) with situations like the ones of interest, and the similarity between the criterion situation and the situation described in the specific measure may attenuate the validity of the specific measures.

It should be noted that the rat situation may have aroused ego threat in addition to rat fear, since many males, and perhaps females as well, may consider it childish or foolish to show fear in such a situation, whether the experimenter is female or male. This may explain the significant correlations between the neuroticism composite and the self-report criterion in this situation. Although the effect of mixed-sex experimenter-subject dyads in this situation, as well as in the other situations, is not known, it seems reasonable to assume, without evidence to the contrary, that subjects would feel equally threatened by potential failure in the presence of a same-sex peer as they would in front of one of the opposite sex.

The findings on the consistency and person-versus-situation issues provided some support for the idea of behavioral continuity (cf. Block, 1971). The indices of consistency suggest that persons' anxiety levels were somewhat generalizable across situations. In addition, analyses of variance on the Mellstrom et al. (1976) data, presented in Zuckerman and Mellstrom (1977), also showed this pattern; the person source explained about 29% of the variance. However, in both studies, when the person source was defined by levels of the traditional A-Trait measures, the percentages of explained variance dropped. In the present study, they dropped from 35% to 12% and 29% to 9% for the hypothetical and actual situation data sets, respectively.

Thus, although some degree of individual consistency of response may exist, we found little predictive power for measures of the trait that is supposed to underlie the consistency. The most likely explanation is that traditional A-Trait tests are not valid measures of the construct that they purport to measure. Alternately, the trait may be more

consistent in some people than in others; that is, some people may be consistent while others are "interactive," being differentially responsive to situations (cf. Bem & Allen, 1974). The specific measures should be predictive for both types of persons as long as the situation is similar to one the person has reacted to on past occasions.

One problem that remains to be resolved is the optimal degree of specificity for prediction. Too broad a definition of situations in the tests may attenuate the predictive potential of the tests, whereas too narrow a definition may limit their usefulness to extremely narrowly defined situations.

INSTRUCTIONS TO AUTHORS

Style of manuscripts. Manuscripts must be prepared in the style described in the *Publishing Manual of the American Psychological Association* (2nd ed.). Instruction on tables, figures, references, metrics, and typing (all copy must be double-spaced) appear in the Manual. Authors should submit manuscripts in triplicate and should keep a copy to guard against loss.

Abstracts. Manuscripts of regular articles must be accompanied by an abstract of 100-175 words. Manuscripts of brief reports must be accompanied by an abstract of 75-100 words. All abstracts must be typed on a separate sheet of paper.

Brief Reports. The *Journal of Consulting and Clinical Psychology* will accept Brief Reports of search studies in clinical psychology. The procedure is intended to permit the publication of soundly designed studies of specialized interest or limited importance which cannot now be accepted as regular articles because of lack of space. Several pages in each issue will be devoted to Brief Reports, published in the order of their receipt without respect to the dates of receipt of the regular articles. Most Brief Reports appear in the first or second issue to go to press following their final acceptance.

An author who wishes to submit a Brief Report:

1. Sends the Brief Report, limited to two printed pages and prepared according to the specifications given below.

2. Agrees not to submit the full report to another journal of general circulation.

Specifications. The Brief Report should give a clear, condensed summary of the procedure of the study and as full an account of the results as space permits.

To ensure that a brief report does not exceed two printed pages, follow these instructions for typing: (a) Set typewriter to a 48-space line. (b) Type text. (c) Count all lines except abstracts, title, and by-line, including acknowledgments. If you have exceeded 185 lines, shorten the material. (d) If your brief report barely exceeds 75 lines (one printed page), try to edit to 75 lines exactly. Reports slightly exceeding one page will be edited for length in order to use space economically.

In Brief Reports, headings, tables, and references are avoided or, if essential, must be counted in the 75 lines. This journal no longer requires an extended report, but, if one is available, each Brief Report must be accompanied by the following footnote:

Requests for reprints and for an extended report of this study should be sent to John Doe (give the author's full name and address).

The footnote should be typed on a separate sheet and not counted in the 75-line quota.

Effect of Subliminal Stimulation of Symbiotic Fantasies on Behavior Modification Treatment of Obesity

Lloyd H. Silverman, April Martin, Roseann Ungaro, and
Eric Mendelsohn

New York Veterans Administration Regional Office, New York, and
Research Center for Mental Health, New York University

In two studies, obese women were treated in a behavior modification program for overeating, in Study 1 for 8 weeks and in Study 2 for 12 weeks. In both studies, the behavior programs were accompanied by subliminal stimulation, with half of the subjects receiving the verbal message MOMMY AND I ARE ONE, intended to stimulate symbiotic gratification fantasies, and the other half, a control message. Weight loss was measured at the end of the program and at follow-up times; in Study 1, 4 weeks after termination and in Study 2, at 4 and 12 weeks posttermination. In both studies the symbiotic condition gave evidence of enhancing weight loss, though it was only at follow-up that the difference between the groups attained statistical significance. This finding, when viewed in conjunction with results from earlier studies of schizophrenics and insect phobics, supports the proposition that the subliminal stimulation of symbiotic fantasies can enhance the effectiveness of therapeutic interventions of various kinds.

During the past 12 years, a research method termed *subliminal psychodynamic activation* has been used in the experimental study of a critical aspect of psychoanalytic theory: the relationship between psychopathological behavior and unconscious libidinal and aggressive wishes. In most of this work, the stimuli were designed to stir up these wishes with the prediction that their subliminal presentation (as compared to the subliminal presentation of relatively neutral stimuli) would measurably intensify particular kinds of psychopathology. In over 20 studies completed to date (summarized in Silverman, 1976),

this expectation has been borne out. The subliminal presentation of a wish-related stimulus produced pathological reactions that did not appear after the subliminal presentation of a neutral stimulus; and in a number of studies, they also did not appear after the wish-related stimulus was presented supraliminally and in the subject's awareness.¹

In another aspect of the research, however, instead of using stimuli designed to *stir up* unconscious wishes and intensify psychopathology, a stimulus was used that was intended

We wish to thank Deborah Brenner, Jill Kline, and Susan Packer for their participation as behavior modification interventionists.

April Martin is now at the Institute for Contemporary Psychotherapy, New York City.

Eric Mendelsohn is now at New York Hospital, Westchester Division.

Requests for reprints, copies of the stimuli used, and other information relevant to replication should be sent to Lloyd Silverman, Research Center for Mental Health, New York University, 6 Washington Place, Room 450, New York, New York 10003.

¹ These studies should be distinguished from the more traditional experiments in the "subliminal area" that have aimed at "finding" the tachistoscopically exposed stimulus (in transformed guise) in the subsequent productions of the subject, rather than at observing its pathological effects. For the reader whose contact with the subliminal area ended with the early skeptical critiques of the phenomenon, see the recent exhaustive and detailed review of Dixon (1971). Finally, for a discussion of why the supraliminal presentation of the same stimuli usually fails to trigger a pathological reaction and why subliminal presentation is then the method of choice for the laboratory study of psychodynamic aspects of psychoanalytic theory, see Silverman (1972).

safely gratify a particular wish and reduce ego pathology. This stimulus was the verbal message MOMMY AND I ARE ONE. Its use was based on the following two interrelated assumptions: (a) The fantasized gratification of the wish for oneness with mommy—the good mother of infancy—can ameliorate ego pathology of various kinds (cf. Silverman, Note 1); and (b) the subliminal presentation of the words MOMMY AND I ARE ONE has the power to activate this fantasy.

In support of the above assumptions, the following can be cited: First, in experiments carried out with eight groups of male schizophrenics (Bronstein, 1976; Kaplan, 1976; Kaye, 1975; Leiter, 1973; Silverman & Cancell, 1970; Silverman, Spiro, Weissberg, & Cancell, 1969; Spiro, 1975), the subliminal presentation of this "symbiotic gratification stimulus" when compared with the (subliminal) effects of a neutral control message has been found to reduce the degree to which ego pathology" is manifested within a laboratory session. Second, with two groups of male homosexuals (research volunteers), another ameliorative effect has been found—a decrease in anxiety and defensiveness within a laboratory session after the subliminal exposure of this same symbiotic gratification message (Silverman, Kwawer, Wolitzky, & Bron, 1973).

In addition to the above findings, there have been three studies in which more than a laboratory effect" has been demonstrated. In one, (Silverman, Frank, & Dachinger, 1974), the effectiveness of the symbiotic gratification stimulus as an aide in the behavioral treatment of insect phobias was demonstrated. Twenty women with insect phobias were seen twice weekly for six sessions. The first and last sessions were for pretreatment and post-treatment assessments of the degree of phobia, with the intervening four sessions for treatment—a variant of systematic desensitization. At each treatment session, subjects viewed scenes of insects that they had previously arranged hierarchically for their anxiety-arousing effects. Subjects began with the least fearful image and progressed to more frightening scenes. After each image, the subjects gave a subjective rating of the degree

of discomfort that they experienced. When discomfort ratings exceeded a specified level, the subjects looked into the tachistoscope for subliminal stimulation. Stimulation was repeated until the discomfort ratings for a particular image were below the criterion level, and subjects then progressed to the next image in the hierarchy. In the usual systematic desensitization paradigm, the imaging is accompanied by deep muscle relaxation. This study substituted subliminal stimulation for the muscle relaxation technique, with the experimental group receiving MOMMY AND I ARE ONE while subjects in the control group received the stimulus PEOPLE WALKING, intended as a (relatively) neutral verbal message. Following the four intervention sessions, on measures of both avoidance and anxiety, the experimental subjects showed a significantly greater degree of improvement of their phobic symptoms than the control subjects.

A second experiment (Silverman, Levinson, Mendelsohn, Ungaro, & Bronstein, 1975) investigated the effects of stimulating symbiotic fantasies during brief therapy with recently hospitalized male schizophrenics. Forty subjects were seen individually, three times a week, over a 6-week period. Treatment consisted of a "fantasy expression" procedure, in which the subjects were shown pictures and were encouraged to fantasize about them, with special emphasis on deriving pleasure from the fantasy and stressing the distinction between fantasy and reality. Half of the subjects were subliminally stimulated with MOMMY AND I ARE ONE several times during each fantasy expression session. The other half received as a control the stimulus PEOPLE ARE WALKING. Pretreatment and posttreatment assessments were made of "ego pathology" on the basis of cognitive and projective tests, interview ratings, and ratings of ward behavior made by the nursing staff. Both groups showed a reduction in the amount of ego pathology in evidence after treatment, but those who had received the experimental stimulus showed a significantly greater reduction.

In the third study (Parker, 1977), two groups of male and female college undergraduates ($n = 20$ in each group), matched

for academic performance, were given tachistoscopic stimulation at the beginning of a class four times a week over a 6-week summer term. For one group the stimulus was MOMMY AND I ARE ONE, whereas for their matched counterparts it was PEOPLE ARE WALKING. The students in the former group received grades on their final exam ("blindly" marked) that were significantly and substantially higher than did the controls (average marks of 90.4% and 82.7%, respectively).²

The present study was intended as an extension of this earlier work with a new subject population—obese women—and accompanying a different intervention—behavior modification training in weight control. It was hypothesized that for persons being treated for obesity with this form of therapy, those whose treatment was accompanied by the subliminal presentation of the symbiotic stimulus would lose more weight than similar persons in the same treatment who were presented with subliminal neutral stimulation. In addition to the point cited earlier about the general ameliorative effects of symbiotic gratification fantasies, the following specific rationale can be offered for predicting such a finding with this population: From psychoanalytic clinical observations of obese patients (Bruch, 1973; Bychowski, 1950), it can be inferred that overeating for the obese person is often motivated by ungratified unconscious wishes for a symbiotic experience. Thus, the fantasied gratification provided by repeated subliminal exposure to the MOMMY AND I ARE ONE stimulus was expected to make their overeating less necessary and thus aid them in successfully using the weight control program.³

Study 1⁴

Method

Subjects. Thirty obese women were recruited through an advertisement in a local newspaper. All subjects were at least 15% overweight, based on the 1959 Metropolitan Life Insurance norms for desirable weights for women (U.S. Department of Health, Education, and Welfare, 1967). Percentage of overweight was determined using the middle weight of the range given for a woman of medium frame at a given height as a baseline. To be eligible for the study, each subject had to state that she felt herself to be an overeater, that she was not currently involved in any organized program of treatment for

obesity, and that she had the time and motivation to attend the treatment sessions. In addition, a brief interview was conducted with each potential subject to screen out psychotic and borderline-psychotic applicants. Four women were excluded on this basis. During the course of data collection, three subjects dropped out after the first session (two of them had been assigned to the experimental group and one to the control), and they were replaced by other applicants.

Subjects were randomly assigned to an experimental and control group. The overall sample ranged in age from 22 to 59, with mean age of 30.7 for the

² In two other recent studies, subliminal symbiotic stimulation has been used with college students. Sackeim (1977) found that within a laboratory session, the MOMMY AND I ARE ONE stimulus heightened self-esteem (as measured by a semantic differential scale). On the other hand, Condon (1976) obtained negative results in attempting to replicate the findings of Silverman, Frank, and Dachinger (1974). Here, it may be important that the population Condon used, unlike the original population, did not consist of persons seeking treatment for their phobias. Instead, the sample was comprised of students who although manifesting a certain degree of phobic symptomatology, entered the study to fulfill a psychology class requirement. It thus may be that subliminal symbiotic stimulation to enhance the effectiveness of a treatment intervention, individuals must be motivated to overcome whatever behavior the treatment is intended to address. Further research is planned to test out this and other possibilities in accord with Condon's nonreplication.

³ The "wishes for a symbiotic experience" referred to above can be seen as related to the "symbiotic phase of development" (cf. Mahler, Pine, & Bergman, 1975), defined as the period of infancy when differentiation from mother and a sense of separateness from her are minimal and most incomplete. The "oneness" with her at this time can serve a number of needs: her presence is guaranteed; her "omnipotence" is shared; nurturance is always available; and she can offer both protection against external dangers and assistance in mastering internal dangers—that is, helping to control unacceptable impulses of various kinds. A legacy of this symbiotic phase of development is the merging wishes referred to above that are viewed as characterizing, to varying degrees, different people throughout their lives. That is, to the extent that needs for protection, omnipotence, nurturance, and so on, are powerful and still sought in the manner of early infancy, wishes for oneness with "mommy" arise. The extent to which they are then gratified depends on the degree of internal conflict such wishes generate as well as on external circumstances.

⁴ This study was part of a doctoral dissertation submitted by the second author (Martin, 1975) in partial fulfillment of the requirements for a doctoral degree at New York University.

experimental subjects and 31.8 for the control subjects. The percent overweight for the sample ranged from 15% to 94%, with means of 40.4% for the experimental group and 42.7% for the control. Neither of these differences approached significance, nor did the difference between the groups in racial composition (93% white). The subjects were asked to estimate the length of time that they have been overweight. The mean number of years estimated for the experimental group was 18.3 and for the control group 19.0, a difference that proved to be nonsignificant ($t < 1$).

Stimuli and tachistoscope. The symbiotic gratification stimulus consisted of the verbal message MOMMY AND I ARE ONE, printed in ink on a white 3×5 card in capital letters with the words MOMMY AND I on one line and the words ARE ONE on a second line. Another card contained the neutral control message PEOPLE WALKING presented on one line. The stimuli were shown through an electronically controlled mirror tachistoscope. The subject looked through an eyepiece at a blank field, and the stimulus was exposed from a second field. The viewing distance was 4 inches (1.3 m), and the surface brightness of a white card for the intensity settings of both fields was 5 ftL (17.1 cd/m²). Exposure time for the stimulus was 4 msec. In previous experiments under these conditions, no subject was able to recognize the content aspects of any stimulus, and less than 10% could discriminate between flashes of light produced by different stimuli (cf. Silverman, 1976).

Procedure. Subjects were randomly assigned to the experimental (symbiosis) or the control group. Two "interventionists," graduate students in psychology, conducted the behavioral treatment sessions, each working with an equal number of subjects in each stimulus group. The interventionists identified the stimuli by code letters appearing on the back of the stimulus cards and remained "blind" throughout the data collection as to which group each subject was in.

Each subject met with her interventionist individually, once a week for 8 consecutive weeks. At each session the subject's weight, in indoor clothing without shoes, was measured using a conventionalathroom scale. Treatment sessions were $\frac{1}{2}$ hour long. The 8-week program was designed to be similar to the behavior modification treatment program for obesity used by Wollersheim (1970). Subjects were instructed on how to keep records of the food they ate and its caloric content, how to systematically reduce the number of situations in which they ate, how to eat more slowly and with more awareness of sensation, and how to reward themselves for appropriate eating behavior. (The structure of the program and the specific techniques used are described more fully in Martin, 1975.)

At the beginning and end of each treatment session, the subject was instructed to look into the tachistoscope for a presentation of the subliminal stimulus. The first presentation was introduced in the following manner: The subject was asked to imagine herself in a situation in which she felt

tempted to overeat. She was asked to describe this situation fully—the place, time, circumstances, the food she was craving, and so on, until she reported that the image was very vivid. For example, she might describe her feeling when seeing cupcakes in the bakery window as she passed it. The experimenter would then say:

People usually feel a kind of tension when they want to eat something but are trying to tell themselves to resist it because they want to lose weight. This is a machine [the tachistoscope] which presents flashes of light. Researchers have found that these flashes can be useful in helping people to relax. If you are able to relax yourself at moments when you are craving something to eat which you know you shouldn't, you will be able to make a calmer decision to resist it. So I want you to look into the viewer, holding that image of the cupcakes trying to say "no" to them. I will say, "Ready, get set," and then you will see a flash of light. I will repeat this for a second flash a few seconds later. I want you to use these flashes to help you relax and walk calmly away from the bakery window.

The subject also was instructed that outside of the treatment sessions, whenever she found herself about to overeat, she should form a mental image of the flash of light she had seen in the machine and then try to refrain from eating. She was told that this would get easier when she had more experience with the flashes and that she would have a chance to see them again at the end of the session and at the beginning and end of every subsequent session. Eventually, it was explained, she would find that as she reached for food in an inappropriate way, she would automatically remember the flash of light and be able to remind herself to return to appropriate eating. The rationale for presenting the subliminal stimulus in this manner was that it served to arouse the subject's tension concerning eating behavior, which then could be reduced by the symbiotic fantasies that were being tachistoscopically activated. Thus, it was analogous to the procedure used in the desensitization study earlier described (Silverman et al., 1974).

Four weeks after the program ended (i.e., 12 weeks after the first session), the subjects returned for a follow-up weigh-in and were debriefed. The debriefing consisted of explaining the rationale for the study, showing both stimuli that had been used and informing each subject of the stimulus to which she had been exposed. Without exception, the subjects expressed surprise and in many instances disbelief that any stimulus had been exposed, insisting that they consciously saw nothing more than flickers of light during the experiment.

Results

Table 1 presents the mean weights of both groups initially, at the end of treatment (8th

Table 1
Means and Standard Deviations of Weight in Pounds for Study 1

	<i>M</i>	<i>SD</i>	<i>M</i>	<i>SD</i>
Pretreatment	181.8	24.6	183.8	40.6
Posttreatment (8th week)	173.8	27.0	178.5	40.7
Follow-up (12th week)	170.9	27.2	179.4	40.9

Note. 1 pound = .4536 kg.

week), and at follow-up (12 weeks). Analyses were carried out in which the initial weights were covaried out of the 8th and 12th week weights.⁵ At the end of treatment, the results, although in the hypothesized direction, were not significant, $F(1, 27) = 1.84$, $p < .18$. At follow-up, however, the difference between the two groups was significant, $F(1, 27) = 7.08$, $p < .01$. As Table 1 indicates, significance was obtained at the latter time because during the 4-week follow-up period, the two groups behaved differently. The experimental group, on the average, continued to lose weight while the control subjects gained. Since the subjects had not been debriefed prior to the follow-up weigh-in, the difference in their eating behavior during the follow-up period can be ascribed to the continuing effects of the differential subliminal stimulation.

Table 2 presents the analogous findings for percent overweight. These results closely parallel the results for actual weight, with the difference between the two groups approaching significance after 8 weeks, $F(1, 27) =$

Table 2

Follow-up (12th week)	32.0	19.9	40.5	27.7

3.75, $p < .06$, and reaching significance after 12 weeks, $F(1, 27) = 9.77$, $p < .004$.

Study 2

This study was intended as a replication and extension of Study 1, with several small changes and additions instituted.

Method

Subjects. Subjects again were recruited through newspaper advertisements. The criteria for selection were the same as in the initial study, except that a more extensive procedure was used for screening out psychotic and borderline-psychotic subjects. Rorschach and figure-drawing protocols were collected in an initial intake assessment, which together with the impression made by the subjects in a brief interview were reviewed by one of the authors (LHS) who has had extensive clinical experience. Six subjects were eliminated on this basis. Of the subjects who began the program, 11 dropped out (5 from the experimental and 6 from the control group) and were replaced. The final sample consisted of 13 subjects in each of the two groups, with mean ages of 31.7 and 36.1 (ages ranged between 22 and 57) and mean percent overweight of 37.9 and 37.4 (percent ranged between 15 and 118) for the experimental and control groups, respectively.⁶ Neither of these differences approached significance, nor did differences between the groups in racial composition (92% white) or in the number of years overweight (mean experimental = 20.1 and control = 21.0).

Stimuli and tachistoscope. The tachistoscopic conditions were identical to those of the initial experiment. However, the control stimulus was slightly altered so that it now consisted of the words PEOPLE

⁵ It is to be noted in Table 1 that with regard to the initial weights of the two groups, although their means were comparable, the standard deviation for the control group was considerably larger than the standard deviation for the experimental group. However, an analysis of covariance still could be carried out, since a test for homogeneity of regression for the two groups revealed that homogeneity was in evidence. Furthermore, with regard to the comparability of the experimental and control groups, for percent overweight (to be discussed) the standard deviations for the two groups were not discrepant.

⁶ In this study (in contrast to Study 1), percent overweight was calculated taking into account the subject's frame (designated as "small," "medium," or "large"). Also, in assigning subjects to the experimental and control groups in Study 2, an effort was made to keep the groups equivalent for actual weight and percent overweight. In Study 1, however, subjects were randomly distributed.

ARE WALKING (instead of PEOPLE WALKING) and was printed on two lines instead of one. This change was made so that the control stimulus would be more structurally similar to the experimental stimulus MOMMY AND I ARE ONE, which was printed on two lines.

Procedure. Four graduate psychology students not associated with the first study served as interventionists. Three were female and one was male, and each saw an equal percent of subjects in the experimental and control groups. As in the first study, the interventionists were blind to the tachistoscopic condition for each subject.

The procedure was identical to that used in Study 1, with the exception that it was extended from 8 weeks to 12 weeks. Also, a second follow-up weigh-in was conducted 8 weeks after the first. Thus, weights were recorded initially, at 12 weeks (when the behavior program and subliminal stimulation ended), after 16 weeks (follow-up 1), and after 24 weeks (follow-up 2). Additionally, to determine whether weight loss would be accompanied by symptom substitution, the subjects also were given a symptom rating scale to fill out at the same four points in time. This was a variant of the Symptom Check List (90 items) (Derogatis, Lipman, Rickels, Uhlenhuths, & Covi, 1974) in which they were asked to indicate on a 5-point scale the degree to which each of 49 psychiatric symptoms were present.⁷

Finally, at the time of the second follow-up, information was elicited from the subjects about the extent to which they had made use of the two aspects of the therapy program during the prior 24 weeks, *outside of the treatment sessions*. That is, they were asked to rate on a 10-point scale, ranging from "not at all" (1) to "extremely frequently" (10), their average weekly use of (a) the behavior modification techniques and (b) the practice of forming mental images of the flashes of light when they were trying to refrain from eating.

Results

Tables 3 and 4 present the data on the actual weight and percent overweight for Study 2. Analyses of covariance revealed that these results closely parallel those from Study 1. At the end of treatment, the differences between the experimental and control groups were not significant on either measure, $F(1, 23) = 2.42$, $p = .130$, and $F(1, 23) = 1.86$, $p = .183$, for actual weight and percent overweight, respectively. However, at the first follow-up 4 weeks later (or 16 weeks after treatment began), both measures attained significance, $F(1, 23) = 5.03$, $p = .033$, and $F(1, 23) = 4.65$, $p = .039$, respectively. At the second follow-up 8 weeks after the first (or 24 weeks after the program began), the

Follow-up 2 (24th week)	153.5	27.5	165.9	28.2

Note. 1 pound = .4536 kg.

difference between the two groups was again significant on both measures, with the means even further apart than they were at the time of the first follow-up, $F(1, 23) = 7.46$, $p = .011$, and $F(1, 23) = 7.40$, $p = .012$, for actual weights and percent overweight, respectively. As in Study 1, the significant differences at the time of follow-up were due to the experimental group subjects', on the average, continuing to lose weight after the behavior treatment sessions ended, whereas the control group gained back some of the weight that had been lost.

On the symptom rating scale, both groups showed a significant reduction in pathology reported from the initial assessment to the 16-week assessment ($t = 2.84$, $p = .015$, and $t = 3.03$, $p = .011$ for the experimental and

⁷ However, sufficient data were available for comparing the experimental and control subjects only initially and at Follow-up 1. At these times the subjects filled out the rating scale in our laboratory, whereas for the postassessment and for Follow-up 2, many subjects took the scales home with them but never returned them. It also should be noted that at Follow-up 2, five subjects (two experimental and three control) could not return to our laboratory for a weigh-in either because they were out of town or because their job situations would not allow it. We contacted them by telephone and asked them to weigh themselves elsewhere and then phoned them a day later for their weights. Although we cannot be certain that the weights they reported would coincide with what their weights would have registered on our own scale, they followed the same pattern as the subjects in their stimulus groups who came in for the weigh-in.

Table 4
Means and Standard Deviations of Percent Overweight for Study 2

Time	Experimental group		Control group	
	<i>M</i>	<i>SD</i>	<i>M</i>	<i>SD</i>
Pretreatment	37.9	26.7	36.3	26.6
Posttreatment (12th week)	28.5	26.5	30.3	26.8
Follow-up 1 (16th week)	26.5	27.9	30.5	26.3
Follow-up 2 (24th week)	25.9	28.3	31.6	25.0

control groups, respectively). The difference in symptom reduction between the two groups was nonsignificant. (With the premeasure covaried out, $F = .024$, $p = .99$.)

Finally, for their ratings (on a 10-point scale) of the degree to which they used the two aspects of the therapy program outside of the treatment sessions, the differences between the two groups were also negligible. With regard to the behavior modification techniques, the average ratings for the experimental and control groups were, respectively, 7.9 and 7.1, and for the use of the mental images of the flashes, 2.8 and 3.2 ($t < 1$ in both instances).

Discussion

It seems warranted to conclude that the 4-msec exposure of MOMMY AND I ARE ONE over several weeks aided both groups of experimental subjects in losing weight. It is true that this conclusion is based on the follow-up weights, but this does not detract from its significance, since there is nothing to indicate that anything other than the subliminal stimuli exposed during the treatment program acted differentially on the groups of experimental and control subjects. In both studies the experimental subjects were given the same behavioral therapy program as the controls, and they had the same number of tachistoscopic exposures by interventionists who were blind to the stimulus messages. In the second study, there were self-report data that indicated that there was no difference in the frequency with which the two groups,

outside of the treatment sessions, used the techniques that they had been taught. Further, since the subjects themselves did not know what stimuli they were receiving, demand characteristics cannot be implicated to account for the significant differences at follow-up. Only the actual content of the stimuli that were subliminally exposed was different for the experimental and control subjects.

The findings from the two studies reported here should be considered in combination with analogous results from investigations with (insect) phobics (Silverman et al., 1974), schizophrenics (Silverman et al., 1975), and undergraduate college students (Parker, 1977) cited earlier. In toto, the results indicate that the subliminal stimulation of the fantasy MOMMY AND I ARE ONE not only can lead to improved adaptation within a laboratory session, as earlier studies of subliminal psychodynamic activation have demonstrated (summarized in Silverman, 1976), but when combined with an intervention that is effective in its own right and when given over a prolonged period of time, this effectiveness is enhanced outside the laboratory. Thus, this intervention can be viewed as having practical utility.

As far as the intervention's utility as an aid in weight control is concerned, it should be noted in the tables that the significant differences that were found were a function of the fact that while the control groups, on the average, regained weight during the follow-up periods, both experimental groups showed further weight loss; and in Study 2, even more weight was lost during the second follow-up period than during the first. This is noteworthy, since as Hall, Hall, Hanson, and Borden (1974) pointed out, it is unusual for obese patients to continue to lose weight during follow-up periods. An examination of the individual data reveals that although only 32% of the control subjects (in both studies combined) accomplished this, 84% of the experimental subjects continued to lose weight. Thus, this experimental intervention may be able to reverse a trend that typically limits the effectiveness of behavior modification treatment of obesity. On the other hand, it also should be noted that the largest (average) weight loss reported for an experimental

group in this pair of studies (15.1 pounds (6.8 kg) or a 12% reduction in weight in Study 2 over a 24-week period) must be viewed as modest and not beyond the range of what has been reported by other (relatively) successful intervention programs for weight control. Thus, if subliminal symbiotic stimulation is to be of substantive value in the treatment of obesity, ways should be sought to increase its potency.

A comparison of the data from Study 1 with that from Study 2 underscores the fact that what led to the differential behavior of the experimental and control subjects during the follow-up periods was not the additional time that elapsed but their response to the nonavailability of treatment. By extending the program an additional 4 weeks in Study 2, the time between the preweights and postweights (12 weeks) was identical to the time between the preweights and follow-up weights in Study 1. Yet even though this extra 4 weeks led to increased weight loss for *both* groups (note in the tables the approximately 30% greater posttreatment weight loss in Study 2 than in Study 1), it did not differentially affect the experimental and control subjects. Thus in Study 2, as in Study 1, the difference between the experimental and control groups did not reach significance until the subjects were on their own for 4 weeks. Apparently, the crucial benefits of the symbiotic stimulation was in allowing the subjects to retain their ability to diminish food intake *in the absence of weekly treatment contact*. Or in psychoanalytic terminology, the presumed activation of the MOMMY AND I ARE ONE fantasy may have allowed the subjects to better internalize the techniques that they had been taught. Whether this was because the therapist was unconsciously equated with "mommy" (whom they now felt more at one with) or for some other reason remains a matter for further study.

A number of other questions also remains to be addressed. First, it would be important to determine from continued follow-ups the duration of the "boost" that the subliminal symbiotic stimulation gives to behavior modification methods in controlling overeating.

Second, there is the question of whether the

diminished overeating brought about by the symbiotic stimulation is at the expense of personality change that could be viewed as maladaptive. In Study 2, the fact that there was no difference in symptom reduction between the experimental and control groups and that, in fact, both groups reported significantly *fewer* symptoms at 16 weeks than they did initially strongly argues against the operation of symptom substitution. However, as one of us has argued elsewhere (Silverman, 1974) in evaluating whether symptom reduction is "gained at a price" as a result of *any* kind of intervention, more than symptom substitution must be evaluated. From what can be observed clinically, the disappearance of symptoms is sometimes accompanied by the emergence of maladaptive behavior that is not experienced as a "symptom." In evaluating any kind of therapeutic intervention, one should investigate whether, and if so to what degree, asymptomatic as well as symptomatic negative personality changes occur when symptoms remit, a practice that we plan to follow in investigations using subliminal symbiotic stimulation.

Third, there is the question of what the precise aspects are of the MOMMY AND I ARE ONE stimulus that account for its effectiveness in weight control. In work with other subject groups, data from several studies have indicated that in order for this stimulus to be ameliorative (when subliminally presented), it must contain a reference to "oneness," but the inclusion of mommy as the person with whom the oneness is achieved is not essential.⁸

⁸ With regard to the results on "oneness," there were two relevant studies. Kaplan (1976) found that while MOMMY AND I ARE ONE reduced pathology in schizophrenics, other reassuring messages involving mommy (e.g., MOMMY FEEDS ME WELL and MOMMY IS ALWAYS WITH ME) did not have this effect. Bronstein (1976) investigated the effectiveness of other "internalization" of mother messages (e.g., MOMMY IS INSIDE ME and MOMMY AND I ARE ALIKE) as well as MOMMY AND I ARE ONE and found that only the latter reduced pathology for schizophrenics. Even though the reference to oneness thus seems to be essential for an adaptation-enhancing effect, data from two other studies indicate that the fantasy of oneness does not have to involve mommy. Kaye (1975) found that the stimulus MY GIRL AND I ARE

Whether the same applies to obese individuals is something we are currently investigating.

There is also an ethical question that can be raised about subjecting people to subliminal stimulation designed to affect their behavior. This issue was dealt with in the current studies by debriefing the subjects at the experiment's conclusion as to the content of their subliminal message and providing them with the opportunity to talk about their reactions. More recently, we have been informing subjects from the beginning that they will be receiving subliminal messages and have found that this does not prevent the MOMMY AND I ARE ONE message from producing its ameliorative effect (Parker, 1977). A further step toward complete openness with subjects that currently is being explored is telling the subjects beforehand which subliminal messages are being used, without telling them which particular message he or she is receiving.

Finally, a question can be raised about what mediates the effectiveness of the MOMMY AND I ARE ONE message as an aid in weight control. Does it act synergistically with the behavior modification techniques, making it easier for subjects to learn and use the latter? Or does it act in a more direct manner by strengthening behavior controls, reducing anxiety, or even by diminishing unconscious symbiotic longings? To make this determination, measures will have to be obtained of the variables just cited in each treatment session, a research strategy that we plan to pursue.

Specific and Nonspecific Factors in the Effectiveness of a Behavioral Approach to the Treatment of Marital Discord

Neil S. Jacobson
University of Iowa

This study compared two behavioral treatments for marital discord with a non-specific control and a waiting-list control. The behavioral treatments combined training in problem-solving skills with training in contingency management procedures, differing only with respect to the contracting form: One group learned to form good faith contracts, and the other, quid pro quo contracts. Thirty-two couples were randomly assigned to one of these treatment conditions and one of three therapists. Improvement was assessed by two observational measures and by two self-report questionnaires. On all measures, both behavioral groups improved significantly more than waiting-list couples. On three of the four measures, behavioral couples improved significantly more than nonspecific couples. The two behavioral groups did not differ from one another on any of the measures.

Although an increasing number of reports have attested to the effectiveness of using social-learning principles in treating marital problems, most of these reports consist of uncontrolled case studies (cf. Jacobson & Martin, 1976). Those few controlled studies attempting to evaluate the effectiveness of such approaches have often been limited

either by equivocal findings (e.g., Harrell & Guernsey, 1976), methodological inadequacies (Tsoi-Hoshmand, 1976), or the analogue nature of the study (Margolin, Note 1).

Despite the lack of definitive evidence in favor of a behavioral approach to marital therapy, the proliferation of suggestive findings warrants cautious optimism. Particularly promising is the combination of training in communication and problem-solving skills with instructions in contingency management procedures, especially contingency contracting (Weiss, Birchler, & Vincent, 1974). A series of impressive case reports (Weiss, Hops, & Patterson, 1973), in addition to Margolin's (Note 1) study, attest to the effectiveness of this combined treatment package.

Jacobson (1977a) evaluated the effectiveness of such a treatment program, comparing it with a minimal treatment, waiting-list control group. On both observational and self-report measures, the couples receiving the behavioral treatment package improved significantly more than did control couples. Within-subject analyses, using data collected by spouses in the home, tended to corroborate the group comparisons. A 1-year follow-up suggested that these positive changes had been maintained.

This manuscript was based on the author's doctoral dissertation, conducted as partial fulfillment of the requirements for a PhD degree. Portions of this article were presented at the meeting of the Association for the Advancement of Behavior Therapy, New York, December 1976. The research was supported by National Institute of Mental Health Research Fellowship 1F31MH05287-01 and by a grant from the Oregon Research Institute.

The author wishes to thank Barclay Martin, the chairperson of his dissertation committee, along with other members of the committee, Judith Flaxman, David Eckerman, Robert Johnson, William Eichman, and William Anderson, for their valuable advice and support. Special thanks are extended to W. Bruce Willingham, who performed invaluable service as chief research assistant; other research assistants to whom the author is indebted are Casey Jacob, Sharon Lorch, Ann Berry, Kurt Nelson, Tim Rodell, and Randy Bernard.

Requests for reprints should be sent to Neil S. Jacobson, Department of Psychology, University of Iowa, Iowa City, Iowa 52242.

Only limited conclusions can be drawn from this initial inquiry. In addition to the small sample size and the inclusion of only one therapist, it is unclear which factors accounted for the effectiveness of the experimental treatment.

The present study served three purposes, two of which followed directly from the limitations of the prior study (Jacobson, 1977a). First, the prior study was replicated, using three therapists instead of one. Second, a group was included that was designed to control for nonspecific factors in the experimental treatment. The group was carefully constructed to control for as many possible competing explanations for change as was feasible, using some of the guidelines suggested by Jacobson and Baucom (1977).

The third purpose of the study was to shed light on a controversy regarding the type of contingency contracting that is most efficacious in the treatment of marital discord. Some (cf. Jacobson & Martin, 1976) have advocated a contracting procedure that Weiss et al. (1974) have referred to as "quid pro quo" contracting. Both partners agree to make a change that the other has deemed desirable; one partner's change serves as a reinforcer for the other's change. Weiss et al. (1974) cautioned against this form of contracting in severely distressed relationships: They argued that the contingent relationship between each spouse's behavior change agreements creates a "who goes first" problem; neither partner is likely to change under such circumstances, given the degree of mistrust in severely distressed relationships. Another potential hazard of quid pro quo contracting is that a failure to change by one spouse sanctions the abdication of the other's contractual responsibilities.

Weiss et al. (1974) advocated an alternative form of contracting, referred to as "parallel" or "good faith" contracting. Here each spouse independently agrees to initiate a change in behavior desired by their partner; rather than the changes being cross-linked to one another, each change is independently reinforced and/or punished.

In Jacobson's initial study (1977a), good faith contracts were used. However, there is no empirical evidence as yet to recommend

the good faith option. Good faith contracts carry with them a distinct disadvantage: They are less efficient, requiring the pinpointing of effective reinforcers and punishers outside the set of target problems defined by the partners. The specification of such consequences can be a cumbersome task. Thus, the present study sought to compare the effectiveness of quid pro quo and good faith contracting procedures.

Couples seeking assistance for relationship problems were randomly assigned to one of three therapists and one of four treatment conditions: a behavioral treatment program using good faith contracts (GF group), a behavioral treatment program using quid pro quo contracts (QPQ group), a nonspecific treatment condition (NS), and a waiting-list control group (WL).

Method

Subjects

Client couples were solicited through three sources: (a) advertisements placed in local newspapers; (b) public service announcements on local radio stations; and (c) referrals from mental health agencies and individual clinicians. The vast majority of couples ($n = 32$) who eventually participated in the study responded to one of the advertisements. The advertisement offered a new experimental treatment for couples experiencing marital problems. Couples were interviewed provided that they had completed the Marital Precounseling Inventory (Stuart & Stuart, 1973), which was mailed to them before the scheduled time of the initial interview.

Therapists

Three therapists treated couples in the study. Two were advanced graduate students in clinical psychology; the other was a master's level social worker. All three had between 2 and 3 years of clinical experience.

I was one of the advanced graduate student therapists. The other two received about 20 hours of training each from me, along with 1-1½ hours of weekly supervision once the study began.

During the first 4 months of the study, couples were randomly assigned either to Therapist 1 or Therapist 2. During the second 4 months of the study, couples were randomly assigned to either Therapist 1 or Therapist 3.

Measures

Marital Interaction Coding System (MICS; Hops, Wills, Patterson, & Weiss, 1971). This was the same behavioral rating system used and described by

Jacobson (1977a). A modified version was used in the present study. Instead of using all 30 behavioral categories, couples' behavior was coded according to 1 of 12 categories; only verbal behavior was coded.

The behavior coded by the MICS consisted of interaction by couples in problem-solving situations before and after therapy. On each occasion, couples were given 5-10 minutes to solve a hypothetical marital problem from the Inventory of Marital Conflicts (Olson & Ryder, 1970) and a "minor" problem in their relationship, which couples chose themselves. These discussions were videotaped and later coded by trained raters who were kept blind to experimental conditions. Reliability was assessed by dividing the frequency with which the two raters agreed that a particular category should be coded by the sum of agreements and disagreements, that is, the number of times a category was marked by one rater but not by the other. This quotient was then multiplied by 100. Both raters coded each discussion for each couple in the study, so that reliability could be continuously assessed. The reliability quotients for particular problem-solving discussions ranged from .56 to 1.00, with an average reliability quotient of .84.

For the purposes of analyses, the 12 categories were further collapsed into 3: positive behavior, negative behavior, and neutral behavior. Positive and negative behavior, recorded in terms of rate per minute, were the two dependent variables derived from the MICS. Scores for husbands and wives were combined so that each couple was analyzed as a unit. Similarly, for a given session, the hypothetical and "real" problems discussed were combined for analysis.

Marital Adjustment Scale (MAS; Locke & Wallace, 1959). This traditional self-report index of marital adjustment was administered to spouses before and after therapy. The scale provides an overall rating of marital satisfaction for each spouse, with a score of 100 (or 200 for a couple) as the cutoff between a satisfying and unsatisfying relationship. For the purposes of analysis, the combined score for the couple was used. This test was administered to couples before and at the conclusion of therapy.

Marital Happiness Scale (MHS). This rating scale is a subscale of Stuart and Stuart's (1973) Marital Pre-Counseling Inventory; couples are required to rate their degree of happiness in regard to 12 general categories of marital life. Since not all 12 items were applicable to all couples, a score for a given spouse was derived by dividing the sum total of the rating for each item by the total number of applicable items, yielding an average rating per item. Then spouse scores were combined, and each couple was analyzed as a unit. Lower scores indicated greater "happiness": The minimum score was 1.00, whereas a maximum score (suggesting maximum "unhappiness") was 5.00.

Manipulation Checks

Posttherapy session evaluation. After each therapy session, all spouses rated both the therapy session and

the therapist on a variety of dimensions, using a questionnaire adapted from Lazarus (1971). Clients' perceptions of the therapist were used as a means of evaluating the degree of stylistic and procedural similarity across therapists. In addition, certain items were used as indirect indices of the credibility of the various treatment conditions.

Descriptions of treatment procedures rated by undergraduates. A group of undergraduate students were randomly presented one of two written treatment descriptions: One described the behavioral treatment condition (without specifying the type of contracting form used), and the other described the non-specific treatment condition. Subjects then completed a brief questionnaire designed to assess the credibility of the procedure as perceived by each subject.

Procedure

At the conclusion of an initial interview, in which a brief history was taken, a set of problems was defined, pretesting was administered (MICS, MAS), and couples were randomly assigned to one of four treatment conditions: GF, QPQ, NS, or WL. WL couples were told that simply experiencing the evaluation and the initial interview had been helpful to some couples, and that they should wait for 8 weeks and then return to decide whether or not they wanted further treatment. Such treatment was offered to couples on their return for posttesting.

For the couples in the other three conditions, a brief description of the research aspects of the program was offered. Procedures subsequently varied depending on the condition to which the couple had been assigned. All treatment groups met weekly for 1-1½ hours, and there were eight treatment sessions in addition to the initial interview.

NS group. Couples in this condition received a treatment devoid of specific instructions in problem-solving and communication skills and without contingency contracting procedures. In all other respects, this condition was designed to duplicate the two behavioral treatment conditions. The condition was roughly equivalent to the behavioral treatment program on the following stylistic and procedural variables:

1. Attention.
2. Expectancies of therapeutic gain. Optimistic and confident statements were identical to those directed toward GF and QPQ couples. The degree to which therapists succeeded in this endeavor was determined by clients' ratings of their therapist following each therapy session. Couples were asked to rate the degree to which their therapists seemed "optimistic" and "confident."
3. Credibility of treatment procedures. Every effort was made to design a treatment condition that would be perceived as credible. To obtain comparative credibility ratings of the various treatment conditions that would not be confounded with outcome, brief descriptions of each treatment procedure were rated as to their credibility by undergraduates.

4. Therapist activity level. In the experimental treatment conditions, the therapist spoke frequently. Similarly, in the NS condition therapists were asked to attempt to intervene as often as they did in GF and QPQ conditions.

5. Directiveness-nondirectiveness. One frequent source of confounding in comparisons between experimental and nonspecific treatment conditions involves the extent of therapist directiveness (cf. Jacobson & Baucom, 1977). Often, therapists in nonspecific conditions are less directive than in corresponding experimental conditions; this difference might be responsible for any discrepancies in treatment effectiveness observed between two groups. Since in the experimental treatment groups the therapy sessions were structured and the therapist actively initiated topics of conversation, such conditions were maintained for NS couples. Client's perceptions of therapy sessions were used to evaluate the therapists' level of directiveness; in posttherapy session questionnaires, clients were asked, for example, "To what extent did the therapist initiate topics of conversation?"

In addition, therapy sessions in the NS condition were structured. In fact, procedurally, the formats of the various conditions were virtually identical. Couples in all treatment conditions were asked to record their change agreements in writing. Also, NS couples engaged in homework assignments between treatment sessions.

6. Opportunity to discuss marital problems.

7. Presentation of a "rationale."

At the conclusion of the initial interview, NS couples were asked to record all "affectionate" acts initiated by the other and to designate each as either "pleasing" or "displeasing." This assignment was ongoing until the end of therapy.

During the initial treatment session, couples were presented with an explanation of the treatment package. The program was presented as an attempt to maximize the effectiveness of many behavior change strategies, each of which by itself has proven somewhat effective in bringing about desirable changes.

The treatment sessions were structured such that problems specified during the initial interview were discussed. Each problem was discussed by the couple until some agreement was reached. The therapist participated actively in such discussions, but at no time did he (she) suggest strategies for solving a particular problem. Nor did he (she) present couples with specific behavioral feedback regarding their performance.

Rather, the therapist's responses were of four types: first, he (she) asked factual questions; second, he (she) restated clients' verbalizations with an emphasis on the apparent "affect" underlying them; third, he (she) made interpretative comments on the basis of the interaction process between the spouses; fourth, the therapist could emit self-disclosing remarks either by offering them a personal reaction to some event in therapy or by offering examples from his (her) own life.

The structure of treatment sessions was identical to

that of the behavioral conditions. At the conclusion of the 8-week program, all couples were offered the opportunity to receive further therapeutic assistance; referrals were arranged by therapists in the study if requests for further therapy were made.

GF group. The treatment program that these couples received replicated the experimental treatment used in the prior study (Jacobson, 1977a) and is described in detail by Jacobson (1977a). Briefly, the first session began with an explanation of the treatment program, including a theoretical rationale. For the remainder of that session and Sessions 2 and 3, couples were taught communication and problem-solving skills, according to guidelines described by Jacobson (1977b, 1977c). Beginning with Session 4, good faith contracting strategies were introduced; for the duration of the treatment program, couples were taught to end their problem-solving sessions with a written agreement specified in the form of a good faith contract. The last treatment session served as a posttest, during which the MAS, MHS, and problem-solving discussions (coded using MICS) were repeated.

Throughout the treatment procedures, couples were assigned problem-solving practice sessions at home between therapy sessions. They kept a notebook to record the details of each practice session.

Skills such as problem solving and good faith contracting were taught using coaching or modeling, and behavior rehearsal (cf. Jacobson, 1977c).

QPQ group. Couples in this condition received treatment identical to that received by GF couples, with one exception: Change agreements taught to couples in this group took the form of quid pro quo exchanges (cf. Weiss et al., 1974). From Session 4 until the end of the treatment program, couples were taught to make exchanges, whereby the husband would make a change desired by the wife in return for a change by the wife desired by the husband. The specified reinforcer in every instance was the change agreed to by the other spouse.

Results

Data Analysis

The primary statistical technique used was multivariate analysis of covariance, with pretest scores on each of the criterion variables used as covariates. Only couples who completed all treatment sessions and were available for posttesting were included in the analysis for treatment effects. Therapist effects as well as Therapist \times Treatment interactions were analyzed with the WL condition excluded. Dropouts were included in this analysis; if such couples were unavailable for posttesting, no change was assumed and posttest scores were assigned that were identical to

pretest scores. Given the small number of couples in each treatment cell, to exclude dropouts would have falsified actual therapist performance, since these were the couples who responded least favorably to treatment. The inclusion of dropouts added two couples to the total sample, adding one GF couple to Therapist 3 and one NS couple to Therapist 2.

Planned comparisons were used for the three individual comparisons of greatest interest (see below), using nonorthogonal contrasts with the alpha level set at .02. Planned comparisons were analyzed using analysis of covariance, with pretest scores serving as covariates. Post hoc comparisons were analyzed using Tukey's honestly significant difference test. For these comparisons, pre-post difference scores were used. Other analyses are described below.

Pretreatment Characteristics of Couples

Demographic characteristics. Couples in the various treatment conditions were compared on age of husband, age of wife, duration of marriage, number of children, and education level for both husband and wife. A multivariate analysis of variance failed to un-

cover differences between treatment conditions on these various measures.

The age of husbands averaged 32.9 years; wives' age averaged 31.8 years. Couples had been married for an average duration of 7.9 years. The number of children averaged 1.32 per couple.

Pretreatment differences on criterion measures. Table 1 shows pretreatment means for all treatment conditions on the four criterion measures used in the study. The overall multivariate test comparing the groups on these measures was nonsignificant.

Therapist Effects

Therapist effects were analyzed by conducting a multivariate analysis of covariance with pretest scores on all dependent measures serving as covariates. WL couples were excluded from this analysis. The test for therapist differences was nonsignificant, $F(8, 20) = .971, p > .50$.

The overall multivariate test for the Therapist \times Treatment interaction was similarly nonsignificant, $F(16, 31) = .41, p > .75$.

Thus, there was no evidence of differential therapist performance. Nor was there any in-

Table 1
Pretreatment and Posttreatment Scores on the Four Dependent Measures for the Four Treatment Groups

Group	n	Negative behavior ^a		Positive behavior ^a		MAS		MHS

Note. Couples were analyzed as a single unit; each mean score represents the combination of a husband's score and his wife's score. GF = good faith; QPQ = quid pro quo; NS = nonspecific treatment; WL = waiting list; MAS = Marital Adjustment Scale; MHS = Marital Happiness Scale.

^a Frequency of behavior emitted (rate per minute).

dication of change in relative therapist performance as a function of treatment condition. Subsequent analyses ignored the therapist factor.

Treatment Effects

A multivariate analysis of covariance was conducted to determine whether an overall treatment effect existed; in this analysis, pretest scores on the four dependent measures were used as covariates. The analysis indicated that a treatment effect did exist, $F(12, 50.56) = 3.36$, $p < .001$. Subsequent analyses specifying the nature of the treatment effect are presented below for each of the criterion measures separately.

Negative behavior. Table 2 indicates the significance tests for each of the four treatment groups in regard to the null hypothesis that the pretest-posttest difference scores were equal to zero for negative behavior. As Figure 1 indicates, the two behavioral treatment groups (GF and QPQ) as well as the

** $p < .005$.

*** $p < .001$.

NS group manifested, on the average, fewer negative behaviors at posttest than during pretest; in contrast, the WL group deteriorated. For both the GF and QPQ groups, the changes were highly significant, whereas for the NS group the changes were nonsignificant. The WL couples' trend toward deterioration bordered on significance. Thus, the only groups that changed significantly in the desired direction, in terms of the frequency of negative behavior, were the GF and QPQ groups.

Planned comparisons of greatest interest were formed. As Table 3 indicates, the two behavioral groups combined were significantly more effective than the WL condition, $F(1, 25) = 31.17$, $p < .001$. Also, the two behavioral groups were significantly more effective than the NS group, $F(1, 25) = 8.80$, $p < .007$. However, there were no significant differences between the two behavioral groups, $F(1, 25) = .49$, $p < .45$.

Post hoc analyses were used for the remain-

Figure 1. Changes in negative behavior for each of the four treatment conditions.

ing paired comparisons.¹ For each comparison, a q statistic was computed using Tukey's honestly significant difference test. Both GF couples and QPQ couples improved significantly more than did WL couples ($p < .01$). However, only GF couples improved significantly more than did NS couples ($p < .01$); although QPQ couples also changed more than did NS couples, the differences did not reach statistical significance. Differences between NS and WL conditions were nonsignificant.

Positive behavior. Figure 2 depicts increases in positive behavior from pretest to posttest for each of the treatment conditions. Again, both behavioral groups changed substantially in the desired direction; this time trends toward deterioration occurred in both the NS and WL conditions. As Table 2 indicates, the changes were statistically significant for both the GF group ($p < .01$) and the QPQ group ($p < .005$).

Table 3 lists the planned comparisons for this measure. The analysis of covariance revealed that the behavioral groups were significantly more effective in increasing positive behavior than either the WL group ($p <$

Figure 2. Changes in positive behavior for each of the four treatment conditions.

$p < .001$) or the NS group ($p < .01$). Using post hoc comparisons, the GF group alone was significantly more effective than the WL group ($p < .01$) and the NS group ($p < .05$). Similarly, the QPQ group was more effective than either the WL ($p < .01$) or the NS group ($p < .05$). Neither the two behavioral groups ($p > .90$) nor the two control groups ($p > .05$) differed significantly from one another.

MAS. Figure 3 shows that on this self-report measure the two behavioral groups again improved substantially from pretest to posttest. With husbands' and wives' scores combined, a score of 200 is generally considered to be the cutoff for a normal degree of marital adjustment. All four of the group means were well below this figure prior to therapy. Only the two behavioral groups averaged above 200 subsequent to therapy. The NS group scores remained virtually the same, but again there was a tendency for WL couples to deteriorate. The only changes that were statistically significant, as indicated by Table 2, were those manifested by GF couples ($p < .001$) and QPQ couples ($p < .001$).

¹For more details, the reader is urged to write to the author, who will provide a way of obtaining a copy of the complete doctoral dissertation.

As with the two observational measures, on the MAS there were no significant differences between GF and QPQ groups. Taken together, the two behavioral groups improved significantly more than did either the WL group ($p < .001$) or the NS group ($p < .002$). Post hoc comparisons revealed that each of the behavioral groups improved significantly more than did the waiting-list group. (In each instance, $p < .01$.) Similarly, each of the behavioral groups improved more than did the nonspecific group ($p < .05$). There were no significant differences between the WL and NS groups.

MHS. In addition to the GF and QPQ groups, who again showed substantial increases from pretest to posttest on reported happiness, the NS group also showed positive changes on this measure; only the WL failed to report such changes. As Table 2 indicates, in each case the improvement manifested by GF, QPQ, and NS groups was statistically significant.

Similarly, as Table 3 indicates, all three of the treatment groups improved significantly more than did the WL group. However, they did not differ significantly from one another. There was a trend favoring the GF group over the QPQ group, and the QPQ group over the NS group, but neither of these trends reached statistical significance.

Follow-up. An MAS form was mailed to each spouse in the GF, QPQ, and NS groups at 1-month, 3-month, and 6-month intervals following the final treatment session. All couples who returned the forms on at least two of the three occasions were included in the follow-up analysis. Of the original sample, only one couple in each of the three treatment conditions was excluded from the analysis. All three of these couples were treated by Therapist 3.

A follow-up score was derived for each couple by averaging the scores on forms returned by each spouse. These averages were then combined so that each couple could be analyzed as a unit.

Difference scores were then computed for each treatment condition by subtracting pretest scores from follow-up scores. An analysis of variance that compared the combined mean

Figure 3. Changes in Marital Adjustment Scale (MAS) for each of the four treatment conditions.

of the two behavioral groups with the mean of the nonspecific group indicated that the groups were significantly different in the direction favoring the behavioral groups, $F(1, 24) = 13.01, p < .002$.

Within-group t tests comparing posttest scores with follow-up scores revealed no significant differences between posttest scores and follow-up scores for any of the three treatment conditions. Thus, the differences favoring the behavioral groups relative to the nonspecific group on the MAS were maintained at the time of the follow-up reports. In addition, group averages on the MAS did not change in any of the three treatment conditions from posttest to follow-up.

Manipulation Checks

Clients' posttherapy session evaluations. After each therapy session, each spouse completed an extensive questionnaire rating the therapist on a variety of dimensions. It was hoped that these ratings would aid in deter-

mining whether (a) therapists performed similarly on relevant stylistic dimensions, (b) behavior was consistent across treatment conditions, (c) the various treatment conditions were equivalent on various nonspecific stylistic and procedural dimensions, and (d) the various treatment conditions seemed equally credible to couples.

A subset of items from the questionnaire was analyzed by a multivariate analysis of variance. The units of analysis were means for each of the 12 items analyzed separately. Husbands' and wives' questionnaires were analyzed separately, and each mean reflected an average rating for a given spouse across therapy sessions. For husbands, the multivariate test was nonsignificant for a treatment effect, $F(24, 8) = .92, p > .50$; a therapist effect, $F(24, 8) = 1.57, p > .25$; and a Therapist \times Treatment interaction, $F(48, 17.45) = 1.27, p > .30$. Similarly, for wives, there was no significant effect for treatment, $F(24, 8) = .95, p > .50$; therapist, $F(24, 8) = 1.58, p > .25$; or Therapist \times Treatment interaction, $F(48, 17.45) = 1.96, p > .05$. Thus, statistical analyses failed to support the notion that clients' posttherapy ratings of their therapists depended on who their therapist was or which treatment condition they were in.

Evaluations of treatment rationales by undergraduate psychology students. After reading a brief description of either the behavioral treatment (with type of contracting unspecified) or the nonspecific treatment, undergraduates answered a seven-item questionnaire designed to assess the apparent credibility of the treatment description. Each of the seven questions was scored separately. Responses for the two groups of subjects were compared using a Hoetelling's T^2 test; the overall test was nonsignificant, $F(7, 121) = .63, p > .70$. On the basis of these responses, it appears that undergraduates found the two treatment rationales equally credible.

Discussion

In the present study, two variants of a behavioral treatment program significantly improved the quality of marriages for couples

who received it. The findings replicated a prior study (Jacobson, 1977a). In addition, a new behavioral condition, using contracts of the quid pro quo variety, was found to be significantly improved relative to the WL group on all criterion measures. The changes achieved by QPQ couples were comparable to those achieved by GF couples.

A nonspecific control group was included in the present study to shed light on the importance of those factors that were theoretically assumed to be the active ingredients of the treatment program. Despite the evidence provided by the manipulation checks suggesting that the NS group was perceived as credible, on three of the four dependent measures the behavioral groups improved significantly more than did the NS group. Only on one of the self-report measures, the MHS, did differences between behavioral and NS conditions fail to reach statistical significance. The MHS asks couples to rate their degree of happiness on a 5-point scale in regard to 12 categories of married life. The purposes of this questionnaire are obvious to clients; the way to score "happy" is clear. Intuitively it would appear that of the four measures, the MHS is most susceptible to demand characteristics. This might explain why the discrepancies between the NS and the behavioral groups were smaller on this measure than on any other. This hypothesis is supported by the finding that the nonspecific group improved *only* on this measure.

The findings of the present study indicate that improvement on the part of behavioral couples cannot be entirely a function of nonspecific factors. On the basis of the manipulation checks, it seems clear that NS couples' expectancies were equivalent to those of behavioral couples. They were as "confident" and as "optimistic" regarding their treatment and their therapist as were behavioral couples. NS couples perceived their therapists as interested and involved to the same degree as did behavioral couples. This was true despite the differential effectiveness of the procedures; although NS couples were not improving, they seemed to be satisfied that they were receiving a competent treatment program administered by involved, concerned, competent

therapists. These results were corroborated by undergraduate students' ratings of therapy rationales for behavioral and NS conditions.

Among couples receiving a behavioral form of treatment, it seemed to make little difference whether they used GF contracts or QPQ contracts. Although these results cannot be taken as conclusive, they tentatively suggest that the two contracting forms are interchangeable. However, it is still possible that GF contracts are preferable for severely distressed couples, a hypothesis consistent with Weiss et al. (1974). A better test of this hypothesis would be to cross severity of marital distress with type of contract used in a 2×2 design. Weiss et al. might predict a significant interaction such that the contract forms would be equally effective for moderately disturbed couples like those in the present study, but for severely disturbed couples GF contracting would yield more effective results.

One problem with the present study was the necessity of using the principal investigator as one of the therapists. However, the data do not support the hypothesis of therapist bias influencing the results. First, the couples' posttherapy ratings did not suggest that any of the therapists behaved differently depending on which treatment program they were implementing. In addition, the absence of Therapist \times Treatment interactions argues against therapist bias. The performance of the principal investigator as therapist, relative to those of the other two therapists, was if anything slightly greater in the NS condition than in the two behavioral conditions.

Another limitation of the present study was the small number of couples per treatment cell in the analysis of therapist effects. Although in all but one instance, at least two couples were treated by each therapist in each treatment condition (Therapist 2 treated only one couple in the NS condition, and this couple dropped out prior to completing the program), the statistical tests for therapist differences were not powerful. It was also unfortunate that dropouts had to be included in the analysis for therapist effects (see Data Analysis section). To not include such couples would have seriously biased the appearance of therapist performance. The assumption of no

change from pretest to posttest for the two dropouts was felt to be a cautious estimate, since all other couples receiving treatment, even those who were considered treatment failures, changed in the positive direction on at least some of the measures.

Future studies should investigate the effectiveness of behavioral marital therapy with severely distressed couples; especially needed are studies involving couples in which one or both spouses present severe behavioral problems apart from relationship distress. Component analyses should also be undertaken to evaluate the particular contributions of problem solving and contingency contracting to treatment efficacy. There is already some convergent evidence that the communication training component (problem solving) is both necessary and sufficient for positive change (Jacobson, in press-b), as well as growing controversy regarding the importance of contingency contracting in a behavioral approach to marital problems (e.g., Jacobson, in press-a). One admittedly speculative but plausible interpretation of the apparent equivalence of good faith and quid pro quo contracts is that contracting per se is unnecessary. Only systematic research can provide a definitive answer to this question.

Toward the Assessment of Social Competence

Robert W. Levenson
Indiana University

John M. Gottman
University of Illinois

Two studies directed toward development and validation of a self-report measure of social competence in dating and assertion situations are described. An 18-item questionnaire consisting of items that assessed the likelihood of certain specific behaviors occurring and the degree of discomfort and expected incompetence in specific situations was derived. This questionnaire discriminated between client and normal populations and between clients with dating and assertion problems, has psychometric properties of reliability and validity, and measures differential improvement following a variety of 8-week intervention programs.

There has been a great deal of recent interest in social skills training, which has been extended from the skill of refusing unreasonable requests (McFall & Lillesand, 1971; McFall & Marston, 1970; McFall & Twentyman, 1973) to more general assertion skills by a number of investigators (Eisler, Hersen, & Miller, 1973; Hersen, Eisler, & Miller, 1973).

The social skills training literature has also expanded to include general social skills training for lower-income clients in mental health centers (Goldstein, 1973), male psychiatric inpatients (Goldsmith & McFall, 1975), and dating skills (Curran, 1975; Curran & Gilbert, 1975; Glass, Gottman, & Shmurak, 1976; Twentyman & McFall, 1975).

In a recent review of social skills training as applied to heterosexual social anxiety, Curran (1977) reviewed 13 studies, concluding that a major issue in the social skills training literature is the assessment of social skills. He noted that "little data exist with regard to the psychometric properties and construct validity of most of the instruments used in previous heterosexual-social anxiety research" (p. 154). Goldfried and Linehan (1977) called for mea-

sures that demonstrate content validity by empirical generation of a content domain (rather than relying on face validity) with attention to the situational context of the behavioral referents assessed. They suggested that discriminant validity studies that demonstrate the separateness of two behavioral concepts will clarify the conceptual ambiguity in behavioral concepts such as assertion.

The present series of investigations is an attempt to develop a self-report assessment measure of social competence that has demonstrated psychometric properties of reliability and validity. Despite the fact that there is a general suspicion of all self-report measures among behavioral scientists, recent research has indicated that under certain specific conditions self-report measures may meet psychometric standards of reliability and validity (Goldfried & Kent, 1972).

Mischel's (1968) review of personality assessment literature led him to conclude that although observation of past behavior in situations with similar role requirements is the best predictor of future behavior in a specific situation, the next best predictor of future behavior is obtained from self-predictions. Furthermore, the research investigations of McFall and his associates have found that although global self-assessments of competence do not relate well to judges' ratings of tapes of behavioral role-playing assessment, self-reports of discomfort and incompetence in *specific* situations (as measured by the Conflict

The authors wish to thank Dave Schlundt, John Embry, Nancy Levin, and Jim Barrett for their help in carrying out this research.

Resolution Inventory) do correlate well with behavioral assessments. For example, McFall and Lillesand (1971) wrote:

The results obtained on the assertive score, nonassertive score, and difference score measures [of the Conflict Resolution Inventory], all of which assessed responses in specific refusal situations, were in sharp contrast to the nonspecific effects obtained on the global measure. (pp. 316-317).

This general finding has been replicated by other investigators (e.g., Schwartz & Gottman, 1976). In a social skills training study with male psychiatric inpatients, Clark (1975) used a global self-assessment of improvement, a situationally specific self-assessment, and a behavioral role-playing assessment. The control group, which received didactic lectures, showed no improvement on the behavioral assessment measure and no improvement on the situationally specific assessment measure but did show improvement on the global self-assessment measure. The social skills training group showed improvement on all three measures. There is thus some initial evidence suggesting that a situationally specific self-report measure of social competence would have validity with respect to laboratory role-playing assessments.

The current investigation requires a self-report measure of social competence to demonstrate several specific kinds of validity. First, it must discriminate between competent and incompetent populations, with competence independently defined. Second, it must discriminate among specific types of social incompetence; for example, nonassertive subjects should show a different scale pattern profile than subjects with heterosexual dating problems. Third, in cases in which treatment is used, the self-report measure must predict differential improvement in treatments designed for the amelioration of specific problems. For example, nonassertive subjects should generally improve on assertion items but not on dating items, compared to dating-problem subjects, who should improve on dating but not assertion items, compared to nonassertive subjects. This latter criterion of validity is dependent on intervention programs that target specific skills for training, and will probably not be met to the extent that dating skills training programs and assertion training programs overlap in the skills they teach.

The present series of investigations was undertaken to design a self-report measure that meets the three criteria of validity described above, as well as internal consistency and test-retest reliabilities. The present investigations also followed the recommendation of Goldfried and D'Zurilla (1969) in empirically constructing a domain of problematic social situations. From this domain, items that involved two specific self-reports were constructed: (a) self-report of discomfort or incompetence—dimensions that have shown validity with behavioral assessments in McFall's Conflict Resolution Inventory—and (b) self-report of the likelihood of engaging in specific behaviors. Items were selected from the larger domain in the two subdomains of assertion and heterosexual dating. A series of reliability and validity studies were undertaken using these items.

Study 1

Method

Subjects

During the second week of the fall 1976 semester, a notice announcing the availability of social skills training programs for students having problems in dating and assertion situations was placed in the student newspaper and posted on dormitory bulletin boards. The approximately 200 students who responded to the notice were mailed a package that included information about the training programs and three questionnaires (described below). Respondents were requested to complete the three questionnaires and return them along with a \$5 deposit if they wished to be included in a training program. They were informed that the deposit would be refunded when they completed a second set of questionnaires at the end of the program. When registration was terminated 3 weeks after the notice first appeared, 92 students had completed the pretest materials, and these students became the "client" population for the study.

At the same time, a group of 69 students who had not signed up for the training program were recruited from the introductory psychology classes and were given the complete set of questionnaires. These students were the "normal" population for the first experiment.

Procedure

Three questionnaires were administered to the client and normal populations: (a) a situations questionnaire, (b) a behavior inventory, and (c) a symptom checklist. A description of these questionnaires follows.

Situations questionnaire (40 items). A domain of items was generated by eight undergraduates (four

males and four females) who signed up for a topical seminar on interviewing. Each member of the seminar interviewed 10 undergraduates and obtained a description of four social situations that the interviewee had recently found to be "difficult to handle." A description of each situation, written by the interviewer, summarized the situational context, the roles of the principal characters in the situation, the action, and the time of key difficulty that preceded a response demanded of the interviewee. The original list of 320 situations was used to generate 97 nonredundant items that could be potentially relevant to both sexes and that struck a balance between being overly general or overly specific. The items were sorted into seven a priori scales by the content of the task posed by the situation: (a) refusing unreasonable requests, (b) getting what you want, (c) expressing how you feel, (d) requesting behavior change from someone, (e) dealing with formal situations (such as a dinner party), (f) initiating and continuing conversations, and (g) dating situations (such as asking for a date and getting close to someone of the opposite sex).

Durham (Note 1) tested these a priori scales with 126 undergraduates. He used three phrasings of the self-report question: (a) a phrasing that confounded discomfort with incompetence,¹ (b) a discomfort phrasing, and (c) an incompetence phrasing. The confounded phrasing showed the best a priori scale test-retest reliabilities (.75) between administrations 3

weeks apart and the best Cronbach alpha coefficient (.97) and split-half reliability coefficient (.94). Using an item analysis of the correlation of items with a priori subscale totals, Durham reduced the original 97-item questionnaire to 40 items. Durham also conducted analyses of selected subject characteristics and found no differences between subjects' scores as a function of sex, year in college, or marital status.

The following excerpt from the social situations questionnaire illustrates the format used:

After each situation, circle one of the numbers from 1 to 5 which best describes you using the following scale:

- 1 = I would be so uncomfortable and so unable to handle this situation that I would avoid it if possible.
- 2 = I would feel very uncomfortable and would have a lot of difficulty handling this situation.
- 3 = I would feel somewhat uncomfortable and would have some difficulty in handling this situation.
- 4 = I would feel quite comfortable and would be able to handle this situation fairly well.

¹ This was the phrasing used in the Conflict Resolution Inventory.

5 = I would feel very comfortable and be able to handle this situation very well.

Your friend's relatives invite you over for dinner. You accept, then begin to feel nervous about making a good impression. You arrive at their house, and everyone sits down to talk before dinner. One of the relatives smiles at you and seems to expect you to say something. 1 2 3 4 5

Behavior inventory (26 items). Construction of the behavior inventory was considerably less formal than that of the social situations questionnaire. Five a priori subscales were established based on five social skills training groups that had been offered by clinical psychology graduate students supervised by us during the spring 1975 semester. The five groups were (a) friendship, (b) self-confidence, (c) assertion, (d) intimacy, and (e) dating. Behaviors that were seen as being particularly difficult for participants in each group were converted into items on the inventory. The inventory was constructed to assess the likelihood of a respondent to exhibit these behaviors. The following excerpt illustrates the nature of the inventory, with examples from the self-confidence, assertion, and dating subscales.

How much were you bothered by:

	Not at all	A little bit	Moderately	Quite a bit	Extremely
Headaches	1	2	3	4	5
Nervousness or shakiness inside	1	2	3	4	5
Trouble remembering things	1	2	3	4	5

Results and Discussion

The presentation of the results is divided into three sections: One section is related to the first validity claim, namely, discrimination of clients from nonclients; one section is related to the second validity claim, namely discrimination of assertion clients from dating skills clients; and a third section is related to psychometric properties of the measures.

Clients and Nonclients

Data were analyzed separately for a priori subscales, individual items (on the situations questionnaire and the behavior inventory) for overall average item score for each questionnaire and for the total symptom checklist score. These data were analyzed in a two-way (clients vs. normals) analysis of variance. An unweighted means solution was used because of the unequal sample sizes. These analyses revealed that clients had greater difficulty on all subscale scores for both the situations

We are interested in finding out something about the likelihood of your acting in certain ways. Below you will find a list of specific behaviors you may or may not exhibit. Use the following rating scale:

1	2	3	4
I never do this	I sometimes do this	I often do this	I do this almost always

Now after each of the items on the following list, place the number which best indicates the likelihood of your behaving in that way. Be as objective as possible.

Volunteer to do something where there is a good chance you might fail. _____

Say "no" when you feel like it. _____

Start a conversation with a member of the opposite sex you would like to date. _____

Symptom checklist (90 items). A questionnaire normally used with hospital inpatients² was adopted for use. Items on this questionnaire reflect anxiety, depression, and somatic symptoms. Subjects rated each item to the extent they are troubled by that problem on a 1 to 5 scale. The following excerpt illustrates the nature of the checklist:

questionnaire and the behavior inventory, greater difficulty on the overall average item score on all three questionnaires, and greater difficulty on 21 of 26 items on the behavior inventory and 35 of 40 items on the situations questionnaire. In all cases, the significance level of these differences was less than .05. Table 1 presents means, *F* ratios, and *p* levels for the subscale and overall average item scores for the clients and normals. The *F* ratios indicate a considerable degree of discriminative power. Note that the means refer to the item scale values described above for each questionnaire and that *smaller* numbers indicate greater difficulty on the situations questionnaire and behavior inventories, whereas *larger* numbers indicate greater difficulty on the symptom checklist.

² This symptom checklist was used as part of a standard clinical intake procedure by the Illinois State Psychiatric Institute and the Family Institute of Chicago.

The results clearly indicate that students who signed up for social skills training reported much greater difficulty across the range of social dimensions measured by our instruments than did normal students. Interestingly, they also reported a greater prevalence of "psychiatric" and somatic symptoms. A picture emerged of a subpopulation that may present itself as generally less socially competent and more problem ridden than its peers.

The results offer some initial validation of the a priori subscales used in the situations and behavior questionnaires: The subscales successfully discriminated between client and normal populations. The first validity criterion was therefore satisfied.

Assertion Clients and Dating Skills Clients

This analysis was carried out using the same data, except that only the 92 clients were used: the assertion groups clients ($n = 46$) and the dating skills clients ($n = 46$).

Two-way (dating subjects vs. assertion subjects) analyses of variance were performed for overall questionnaire scores, a priori subscales, and individual items. Results indicate

that dating subjects showed significantly greater difficulty as compared to assertion subjects on the dating subscales of both the situations questionnaire and the behavior inventory. Assertion subjects showed significantly greater difficulty on the "self-confidence" and "assertiveness" subscales of the behavior inventory. Means, *F* ratios, and *p* levels are presented for these differences in Table 2. Analysis of the individual items revealed that 8 of 40 items on the situations questionnaire and 8 of 26 items on the behavior inventory significantly differentiated dating subjects and assertion subjects at $p < .05$.

Knowing the training program for which clients had registered allowed a second empirical test of the validity of several of our subscales. The results of this experiment indicate that clients with dating and assertion problems tend to score accordingly on dating-related and assertion-related subscales. Moreover, the use of two different kinds of self-report measures (i.e., the situations questionnaire and behavior inventory), and the tendency of clients to score appropriately on both, provided us with convergent evidence that true differences existed between the dating and

assertion subpopulations and that these were measurable independently using self-report measures.

To enhance the validity of the dating and assertion scales, we decided to focus on the dating and assertion subpopulations, to concentrate on developing one questionnaire containing only the dating and assertion subscales, and to subject this new questionnaire to standard reliability tests prior to continuing with additional validation procedures.

Psychometric Properties

An 18-item questionnaire was developed with a 9-item dating subscale and a 9-item assertion subscale. This new questionnaire was tested scalewise for internal consistency and test-retest reliability. In addition, previous validity tests for discriminating clients versus normals and dating versus assertion problems were recomputed using these new subscales.

The original 92 clients (46 dating, 46 assertion) and 69 normals were studied again for computing internal consistency and for performing concurrent validity checks. Seventy additional subjects who had not registered for the training programs were recruited from the introductory psychology classes to serve as a sample for performing a test-retest reliability analysis.

The original 26-item behavior inventory and 40-item situations questionnaire were transformed into an 18-item questionnaire by selecting only those items that both successfully discriminated clients from normals and successfully discriminated dating clients from assertion clients. Of the 18 items that met these criteria, dating clients indicated having greater difficulty with 9 of the items (5 from the original behavior inventory and 4 from the original situations questionnaire), whereas assertion clients indicated greater difficulty with the other 9 (4 from the original behavior inventory and 5 from the original situations questionnaire). Thus, these sets of items became our 9-item dating and assertion subscales (see Appendix), which were tested for their psychometric properties as follows: (a) A Cronbach alpha was computed for assessing the internal consistency of the dating and assertion subscales using the data from the

original clients and normals; (b) comparisons of clients versus normals and of dating clients versus assertion clients were made on the two subscales using the original client and normal sample; (c) to assess test-retest reliability 6 weeks prior to the end of the semester 44 normal subjects were administered the original test battery. An additional 30 normal subjects took the test battery 4 weeks later. All 70 subjects took the battery again 2 weeks later. Usable data were obtained from 28 subjects for the 2-week test-retest interval and from an independent group of 39 subjects for the 6-week interval.

Analysis of internal consistency yielded a Cronbach alpha of .92 for the dating subscale and an alpha of .85 for the assertion scale. Concurrent discriminant validity analyses revealed clients to have significantly greater difficulty than normals on both the dating subscale, $F(1, 159) = 52.60$, $p < .001$, and the assertion subscale, $F(1, 159) = 34.33$, $p < .001$. Dating clients had more difficulty than assertion clients on the dating subscale, $F(1, 86) = 17.55$, $p < .001$. Assertion clients had more difficulty than dating clients on the assertion subscale, $F(1, 86) = 21.00$, $p < .001$.

To assess test-retest change, a 2×2 (2 Week vs. 6 Week \times Pretest vs. Posttest) analysis of variance was computed for the 2-week and 6-week groups. The results indicated no change at retesting at either interval for either the dating subscale or the assertion subscale. The test-retest correlations for both subscales at both testing intervals ($ns = 28$ and 39, respectively) were: For dating at 2 and 6 weeks, $rs = .71$ and $.62$. For assertion, $rs = .71$ and $.70$ ($p < .001$).

The results indicate that the dating and assertion subscales have demonstrable psychometric qualities of reliability and validity. Of particular interest was the finding that the scales had internal consistency despite the fact that items were selected on the basis of their ability to discriminate between populations. This suggests that the scale items are in fact measuring the same dimension and that this dimension is one for which salient differences do exist between the populations in question.

The test-retest experiment was performed to determine whether the subscales would fluctuate greatly over the measurement periods

in question. Especially important for Study 2 was the determination of whether significant changes in self-report of dating and assertion difficulties would occur at the end of semester approached. On the basis of our findings, there is no reason to expect these kinds of difficulties to spontaneously increase or decrease over the course of our testing intervals. However, these test-retest data were obtained using normal subjects, and their applicability to client populations was not tested.

Study 2

In this section the results of an 8-week intervention directed toward amelioration of specific social skills problems is presented. This intervention was used to test the abilities of our instrument to measure differential changes as a function of the type of social skills training program.

Method

Procedure

The 46 dating clients who had completed the pretest materials in Experiment 1 were assigned to one of three treatment conditions: (a) group meeting ($n = 11$), (b) self-help manual plus consultant ($n = 11$), or (c) self-help manual ($n = 24$).

In a similar manner, the 46 assertion clients were assigned to either group meeting ($n = 8$), self-help manual plus consultant ($n = 12$), or self-help manual ($n = 26$) conditions. A description of the three treatment conditions follows.

Group meeting. Clients assigned to this condition attended weekly 90-minute sessions for 8 weeks under the leadership of male and female cotherapists. The focus of these groups was on behavioral rehearsal, role-playing, and skill acquisition exercises.

Self-help manual plus consultant. Original manuals were written that contained information and exercises relevant to assertion skills and dating skills.³ These manuals were divided into eight sections, with each containing information and exercises for 1 week.

In addition to the manual, clients in this condition were assigned an undergraduate "consultant" who met with the client at the start of the 8-week period, called them periodically to check on their progress, and was available for phone consultation if the client so desired.

Self-help manual. Clients in this condition received the appropriate self-help manual as in the previous condition but were not assigned a consultant.

At the end of the 8-week period, all clients in all conditions were mailed a package of posttest questionnaires and were reminded that their \$5 deposits would be refunded as soon as the materials were completed and returned.

Table 3

Pretest and Posttest Subscale Scores for Dating and Assertion Clients

Group	Dating	Assertion
Dating		
Pre (46)	1.95	2.91
Post (38)	2.41	3.02
t	5.55*	1.34
Assertion		
Pre (46)	2.45	2.48
Post (35)	2.76	3.02
t	3.75*	6.51*

Note. Numbers in parentheses are n s.

* $p < .001$.

Results and Discussion

We were able to obtain a fairly high rate of return from clients completing the program for our posttest materials. There was also a small number of clients who chose to drop out of the program prior to its completion. The overall return rate was 79%, and by treatment was group meeting (89%), self-help manual plus consultant (78%), and self-help manual (76%).

Data obtained from these clients were analyzed in a 2×2 (Dating Clients versus Assertion Clients \times Pretest versus Posttest) analysis of variance for the dating and assertion subscales. Results indicated a significant pretest versus posttest main effect for both the dating subscale, $F(1, 67) = 48.31$, $p < .001$, and the assertion subscale, $F(1, 67) = 37.87$, $p < .001$. Significant Client \times Test interactions were obtained for the dating subscale, $F(1, 67) = 4.40$, $p = .037$, and for the assertion subscale, $F(1, 67) = 21.11$, $p < .001$.

Of greatest interest for the present investigation were the data concerning changes on the dating and assertion subscales for clients working in dating and assertion training programs. Pretest and posttest means for these clients and subscales are presented in Table 3. These results indicate that significant improvement occurred only for the dating subscales for dating clients. Assertion clients improved

³ The authors are extremely grateful to John Embry, Jennifer Parkhurst, and David Schlundt who helped write and edit the manuals.

on both subscales but showed more improvement on the assertion scale than on the dating scale.

The results obtained from Study 2 indicate measurable improvement in both client populations over the 8-week period. Despite the fact that a no-treatment control was not included, it can be argued for several reasons that these changes are most readily attributable to the interventions that occurred during this period. First, the most pronounced change occurred on the subscale related to the targeted problem. This was especially true for the dating clients, who showed no change on the assertion subscale. In addition, test-retest data on normal subjects in Study 1 over a similar time period indicated no change on either subscale. There is little reason to expect that client populations would spontaneously improve over this time period.

Study 2 provides an extension of the utility of the dating and assertion subscales. Prior to initiating these pretreatment versus post-treatment comparisons, we were not optimistic about the likelihood that these subscales would be useful for measuring change following an 8-week intervention. It had seemed to be the case that the utility of a scale to register changes on a personality dimension was quite independent of its ability to satisfy static criteria of reliability and validity. The additional expectation of differential changes as a function of specific types of intervention thus serves as an additional validity check. The discriminant validity of the dating and assertion scales may clarify the frequent ambiguity inherent in the behavioral concept of social skills; it would seem reasonable to hypothesize that social competence consists of a set of relatively independent skills.

This article is a step toward the assessment of specific aspects of social competence. We should add that these two scales should be used cautiously; the two questionnaires contain a narrow sampling of items from a larger domain (cf. Durham, Note 1) and should not be equated with social competence. We also stress the limitation of this article in only using self-report measures in the validation procedure. Still to be demonstrated is that these measures correlate with relevant extralaboratory criteria and with measures obtained by coding behavior samples.

Our primary interest was the construction of measures that successfully differentiate people who have a given difficulty from those who do not, that discriminate among people who have different kinds of related difficulties, and that indicate change in the level of this difficulty differentially as a function of the treatment received. The results of the studies presented here indicate that one kind of self-report measure that satisfies all of these criteria can be constructed by assessing the likelihood of certain behaviors occurring and the degree of discomfort and expected incompetence in specific situations. A useful assessment device was thus constructed from items that combined behavioral specificity with the phenomenology of expected difficulty and discomfort.

Appendix

Dating and Assertion Questionnaire (18 items)

We are interested in finding out something about the likelihood of your acting in certain ways. Below you will find a list of specific behaviors you may or may not exhibit. Use the following rating scale:

- 1 = I never do this
- 2 = I sometimes do this
- 3 = I often do this
- 4 = I do this almost always

Now after each of the items on the following list, place the number which best indicates the likelihood of your behaving in that way. Be as objective as possible. [Subscale loadings for items are indicated in parentheses. A = assertion subscale; D = dating subscale.]

1. Stand up for your rights (A)
2. Maintain a long conversation with a member of the opposite sex (D)
3. Be confident in your ability to succeed in a situation in which you have to demonstrate your competence (A)
4. Say "no" when you feel like it (A)
5. Get a second date with someone you have dated once (D)
6. Assume a role of leadership (A)
7. Be able to accurately sense how a member of the opposite sex feels about you (D)
8. Have an intimate emotional relationship with a member of the opposite sex (D)

9. Have an intimate physical relationship with a member of the opposite sex (D)

The following questions describe a variety of social situations that you might encounter. In each situation you may feel "put on the spot." Some situations may be familiar to you, and others may not. We'd like you to read each situation and try to imagine yourself actually in the situation. The more vividly you get a mental picture and place yourself into the situation, the better.

After each situation circle one of the numbers from 1 to 5 which best describes you using the following scale:

- 1 = I would be so uncomfortable and so unable to handle this situation that I would avoid it if possible.
- 2 = I would feel very uncomfortable and would have a lot of difficulty handling this situation.
- 3 = I would feel somewhat uncomfortable and would have some difficulty in handling this situation.
- 4 = I would feel quite comfortable and would be able to handle this situation fairly well.
- 5 = I would feel very comfortable and be able to handle this situation very well.

1. You're waiting patiently in line at the checkout when a couple of people cut right in front of you. You feel really annoyed and want to tell them to wait their turn at the back of

the line. One of them says, "Look, you don't mind do you? But we're in a terrible hurry."

1 2 3 4 5 (A)

2. You have enjoyed this date and would like to see your date again. The evening is coming to a close and you decide to say something.

1 2 3 4 5 (D)

3. You are talking to a professor about dropping a class. You explain your situation, which you fabricate slightly for effect. Looking at his grade book the professor comments that you are pretty far behind. You go into greater detail about why you are behind and why you'd like to be allowed to withdraw from his class. He then says, "I'm sorry, but it's against university policy to let you withdraw this late in the semester."

1 2 3 4 5 (A)

4. You meet someone you don't know very well but are attracted to. You want to ask them out for a date.

1 2 3 4 5 (D)

5. You meet someone of the opposite sex at lunch and have a very enjoyable conversation. You'd like to get together again and decide to say something.

1 2 3 4 5 (D)

6. Your roommate has several obnoxious traits that upset you very much. So far, you

have mentioned them once or twice, but no noticeable changes have occurred. You still have 3 months left to live together. You decide to say something.

1 2 3 4 5 (A)

7. You're with a small group of people who you don't know too well. Most of them are expressing a point of view that you disagree with. You'd like to state your opinion even if it means you'll probably be in the minority.

1 2 3 4 5 (A)

8. You go to a party where you don't know many people. Someone of the opposite sex approaches you and introduces herself. You want to start a conversation and get to know him/her.

1 2 3 4 5 (D)

9. You are trying to make an appointment with the dean. You are talking to his secretary face-to-face. She asks you what division you are in and when you tell her, she starts asking you questions about the nature of your problem. You inquire as to why she is asking all these questions and she replies very snobbishly that she is the person who decides if your problem is important enough to warrant an audience with the dean. You decide to say something.

Behavior Modification for Obesity: The Evaluation of Exercise, Contingency Management, and Program Adherence

Peter M. Stalonas, Jr.
University of Rochester

William G. Johnson
Department of Psychiatry and Human Behavior
University of Mississippi Medical Center

Maryann Christ
University of Rochester

This study investigated crucial aspects of behavioral programs for obesity including (a) the assumption that subjects actually engage in requested behaviors and that these behaviors mediate weight loss, (b) the effect of exercise on weight loss, and (c) the problem of long-term maintenance and generalization to the clinically obese. Exercise and self-managed contingency components were compared in a 2×2 factorial design on 44 obese subjects and were evaluated after 10 weeks of treatment and 3-month and 1-year follow-ups. Significant weight loss was observed for all groups at program termination ($p < .001$) and the 3-month follow-up ($p < .001$), with only those exposed to exercise and/or contingency management maintaining weight loss after 1 year. There were no main effects or interactions at program termination or at the 3-month follow-up. However, the influence of exercise at the 1-year follow-up was noticeable ($p < .10$). Assessment of program adherence indicated that subjects engaged in program behaviors, yet only 1 of 10 such behaviors was related to weight loss.

Recent reviews of behavior modification for obesity support the superiority of this approach relative to other treatments (Leon, 1976; Stunkard, 1975). However, several important issues regarding the evaluation of the behavioral approach remain. These include (a) a common and perhaps erroneous assumption that subjects actually engage in program behaviors and that these behaviors mediate weight loss, (b) the failure to evaluate the influence of exercise, (c) long-term evaluation, and (d) the use of clinical as opposed to student populations.

The first issue of subject compliance is highlighted by a survey of over 20 recent reports

on the behavioral management of obesity (Johnson & Stalonas, Note 1). Only 3 of these reports supplied information relevant to whether subjects actually engaged in the behavioral changes suggested. For example, studies by Hall, Hall, Hanson, and Borden (1974); Horan, Baker, Hoffman, and Shute (1975); Jeffrey (1974); and Mahoney, Moura, and Wade (1973), while demonstrating weight loss, either provided no information on program adherence or were limited to post hoc reports (Bellack, Rozenky, & Schwartz, 1974; Mahoney, 1974) or pre-post questionnaires on eating habits (Wollersheim, 1970). Thus, information supporting the claim that participants actually use behavioral strategies is notably lacking in the published literature. Investigators may be incorrectly inferring the operation of independent variables embodied in these programs on the basis of weight change alone (Mahoney, 1975).

A second issue in the treatment of obesity is the influence of exercise. Low levels of energy expenditure are typical of the obese, and Mayer

Senior authorship is shared by the first two authors. Portions of this article were presented at the annual meetings of the Southeastern Psychological Association, New Orleans, March 1976, and the American Psychological Association, Washington, D.C., September 1976. (1968), among others, indicated that this relative inactivity is a major factor in the development of obesity. Exercise not only increases caloric expenditure and the metabolism of fat, but it also decreases appetite, aids in cardiovascular conditioning, and generally promotes a sense of psychological well-being (Björntorp, 1976; Horton, 1974). Thus, the direct health benefits of exercise are obvious and strongly implicated as an important adjunct to weight reduction.

In spite of its appeal, the contribution of regular exercise to weight loss has been evaluated in only one study. In this study, Harris and Hallbauer (1973) found no difference at the termination of a 12-week program between *controlled eating* and *controlled eating plus exercise* groups. However, the group that exercised lost significantly more weight at a 7-month follow-up than the comparison group. This study stands in virtual isolation, and a replication of the exercise effect is indicated particularly in light of its potential contribution to the maintenance of weight loss.

The third issue is the evaluation of subjects over an extended period of time. The overwhelming majority of studies on weight reduction follow subjects for 3 months or less. For the clinically obese who are often 50% over their ideal weight, long-term follow-up of at least 1 year is necessary to consider program efficacy.

Finally, past research on obesity has been largely limited to subjects in college settings. Evaluation of the effects of a behavioral weight loss intervention on community members of varying ages and socioeconomic classes is necessary if we are to address the generalized utility of such programs.

The present study confronted these crucial aspects of behavioral approaches to weight reduction by attempting to (a) ascertain the relationship between ongoing reports of program adherence and weight loss; (b) assess the effectiveness of exercise; (c) plan long-term evaluation; and (d) use a clinical, nonstudent population.

Method

Subjects

Forty-eight subjects responded to local advertisements of a free program for weight loss. During the

first 3 weeks of the program, 4 subjects dropped out due to scheduling or health problems, leaving 44 subjects who met the following requirements: (a) at least 15% overweight based on figures tabulated by the Metropolitan Life Insurance Company (1959), (b) free of complicating health disorders and medication, and (c) no prior experience with formal behavioral programs for weight loss.

Subjects averaged 31.5 years of age (range = 16-62), 181.1 pounds (82.1 kg) (range = 130-275 pounds) (59.0-124.7 kg), and 40.2% overweight (range = 15%-112%). There were 37 female and 7 male participants who were from socioeconomic status Levels I to IV (Hollingshead & Redlich, 1958) with 2, 19, 21, and 2 members per level, respectively.

Procedure

Subjects were randomly assigned to four groups (matched on age, sex, absolute weight, and overweight) in a 2×2 factorial design. Also, baseline levels of activity were assessed, and mean expenditures for the four groups were equivalent. All groups received a similar weight loss program (P) with the following exceptions: One group received the addition of both exercise and contingency components (PEC), a second group received the addition of just exercise (PE), a third group received the addition of just a contingency component (PC), and the final group was exposed to the basic program alone (P).

The basic program used in all four groups consisted of 10 written lessons (Johnson & Stalonas, in press) that describe a sequence of behavioral tasks including monitoring all information related to eating; advice on the components of a balanced diet; making salient those activities that might inhibit eating; eating at specific times, places, and situations; manipulating elements in the eating chain; imagining aversive stimuli contingent on inappropriate urges to eat; and graphing the use of program behaviors.

The exercise component consisted of specific attempts to increase weekly levels of physical activity. PEC and PE groups were given a list relating activities to caloric expenditures and were encouraged to increase their physical activity over a 10-week period from 150 to 400 kcalories (630-1,680 J) per day above their basal level.

The contingency manipulation consisted of instruction in the use of self-reinforcement for successfully applying the strategies of the program. Subjects in the PEC and PC groups compiled lists of activities that could serve as self-administered rewards. In the third week, these subjects completed daily checklists in which program activities were converted into points that could be exchanged for daily (e.g., reading a chapter of a book) and weekly rewards (e.g., buying a new dress).

Group Meetings

The four groups of subjects attended 10 weekly 1-hour sessions, which were conducted by two experi-

enced coleaders. To maximize attendance, subjects deposited \$10, of which \$1 was returned each week. This procedure resulted in an average attendance for all subjects of nine meetings.

The first part of each meeting was directed toward an extensive, individual review of performance records, charts, and weights with one of the two therapists. Thereafter, a group discussion ensued regarding progress, areas of difficulty, and suggestions with liberal administrations of verbal encouragement and support. Toward the end of the group meeting, the next lesson was distributed and explained.

Results

There were two main sources of data—weight change and program behaviors. For weight change, data were available for Week 1 through program termination at Week 10, a 3-month follow-up, and a 1-year follow-up. Data regarding program behavior adherence are available for Week 1–Week 10. Of the 44 subjects completing the program, one subject was unavailable at the 3-month follow-up due to pregnancy, and two additional subjects had left the country at the 1-year follow-up.

Weight Loss

Mean weight changes for each of the four groups over three time periods are presented in Table 1. These changes were analyzed in three separate 2×2 analyses of variance for each time period.¹ The main effects of contingency management and exercise and the interactions did not reach significant levels in any analysis. There was a nonsignificant tendency, however, toward a main effect of exercise for Week 1 to the 1-year follow-up, $F(1, 37) = 3.0, p < .10$.

Correlated t tests were performed for each of the four groups separately. As Table 1 reveals, each group lost a significant amount of weight at program termination. ($M = 10.7$ pounds (4.8 kg) for the four groups taken together, $p < .001$.) This weight loss amounts to a decrease of 8% in excess weight.

At the 3-month follow-up, average weight changes for each group remained significant at the .001 level, with the total weight loss averaging 12.50 pounds (5.7 kg). Although there were no significant differences between Week 10 and the 3-month follow-up for any group, most subjects maintained the weight

Table 1
Mean Weight Loss

Group	Week 10	Follow-up	
		3 mo.	1 yr.
PEC	9.5***	12.4***	13.1**
%	10	10	10
PE	13.1***	14.9***	16.3*
%	10	9	9
PC	10.0***	13.4***	11.4***
%	12	12	10
P	10.3***	9.9***	5.2
%	12	12	12

Note. PEC = program with exercise and contingency components; PE = program with just exercise; PC = program with just the contingency component, and P = the basic program alone.

** $p < .01$.

*** $p < .001$.

loss engendered during the program or continued to lose weight.

Data available at the 1-year follow-up revealed a similarly striking yet less consistent pattern of maintained weight loss. As Table 1 illustrates, the three groups exposed to contingency and/or exercise components were able to maintain their weight loss. In contrast, the P group, exposed to only the basic training in stimulus control, displayed an average weight increase of 4.7 pounds (2.1 kg) from the 3-month to the 1-year follow-up.

Program Adherence

The performance of program behaviors was assessed on the basis of weekly reviews of each subject's recordings and graphs. Ratings were made of stimulus control, notebook recordings, self-monitoring with graphs, chaining, timeouts, one portion of food per meal, caloric monitoring, between-meal uncontrolled eating, exercise, and self-administered reinforcement. With the exception of exercise and uncontrolled eating, program behaviors were rated on a 3-point scale based on the number of days per week in which the behavior was performed

¹ Statistical analyses were also performed on percent overweight and Feinstein's (1959) weight reduction index with results virtually identical to those for weight change.

correctly. One point was awarded for 6 or 7 days, $\frac{1}{2}$ point for 4 or 5 days, and no points were given for less than 4 days of proper execution of the behavior in question.

Ratings of exercise and uncontrolled eating were based on actual frequency counts obtained from graphs. For exercise this consisted of a proportion of the total caloric expenditure expected during the program to the number of calories actually performed. Subjects who ate uncontrollably once in a given week received 1 point, twice earned $\frac{1}{2}$ point, and more than twice in a given week earned no points.

These program adherence scores varied from 1.0 to .0. The actual mean scores ranged from a low of .57 for uncontrolled eating to a high of .94 for eating one portion, with the mean for all program behaviors together being .82. It is clear that within the limitations of these self-report data, subjects performed the required program behaviors at or near an optimal level.

Because the distributions of adherence were positively skewed, an arc sine transformation was used to achieve more variability. The transformed measures of program behavior adherence were correlated with weight loss at Week 10, and only uncontrolled eating was significantly correlated with weight change ($r = .29, p < .05$).

With the exception of exercise and self-reinforcement, which were administered to only half of the subjects, the combined relationship of the program adherence measures to weight change was evaluated in a multiple regression analysis. This multiple correlation accounted for an insignificant amount of the variation in weight change at Week 10 ($R^2 = .229, R^2 = .042$). In addition, average adherence scores generated for each subject correlated insignificantly with weight change.

Discussion

Our subjects lost an average of 10.7 pounds (4.8 kg) at program termination, which represents a significant reduction over their initial weight. These results are consistent with previous reports on behavioral approaches to weight reduction, which indicate that subjects lose an average of 1 pound (.45 kg) per week (Leon, 1976; Stunkard, 1975).

Even though these data are noteworthy, other weight reduction regimens such as anorectic drugs and special diets also produce weight loss during their implementation. In most cases, however, once the drug or diet is relinquished, weight gain ensues (Chlouverakis, 1975). So, although behavioral approaches are similar to other forms of weight reduction in demonstrating weight loss during active treatment, whether they foster maintenance of weight loss following program termination is another question.

Maintenance of Weight Loss

To evaluate maintenance, we assessed our results with both 3-month and 1-year follow-ups. The data at the 3-month follow-up show the efficacy of all treatment conditions. Regardless of whether a subject was exposed to the basic program, exercise, contingency management, or some combination thereof, weight loss, on the average, exceeded that at program termination. Of the four conditions, only the *P* group displayed a slight increase (.4 pounds (.2 kg)) over this 3-month period. More importantly, at the 1-year follow-up, treatment gains were maintained in our PEC, PE, and PC groups.

In the studies surveyed by Leon (1976), only four are reported with at least a 6-month follow-up. In Stuart's (1967) report, a mean weight loss at 1 year of 37.7 pounds (17.1 kg) was observed for eight subjects. Comparison with our data is difficult due to the variability in subject sessions (16-41) and the scheduling of maintenance sessions as needed. Also, Mahoney (1974) reported that subjects in an eating habit change group lost 8.3 pounds (3.8 kg) after an 8-week program. At the 1-year follow-up, 70% of these subjects maintained their lower weights or continued to lose. More recently, McReynolds, Lutz, Paulsen, and Kohrs (1976) reported over 17 pounds (7.7 kg) lost after a 15-week program, 19 pounds (8.6 kg) at 3 months, and 17 pounds (7.7 kg) at a 6-month follow-up. Subjects in our PEC, PE, and PC groups performed similarly to those in the McReynolds et al. and Mahoney studies both in terms of the maintenance of weight loss and the percent of subjects maintaining lower weights. Seventy percent of our subjects

(PEC, PE, PC) maintained their lower weights or continued to lose at 3 months and 65% at the 1-year follow-up.

Even though it is clear that most subjects lose weight when involved in the program and many are able to keep it off for extended periods, their ability to *continue losing weight* after program termination is more questionable. Twenty-nine percent of our subjects lost as much as 5 pounds (2.3 kg) more after program termination, whereas only 20% of them were able to lose as much as 10 pounds (4.5 kg) more. Thus, although our subjects were able to maintain their weight loss, less than one third lost a substantial amount of additional weight. Since they averaged approximately 40% overweight, few of them reached their desirable weights over the 1-year time period. In terms of a decrease in percent overweight, the PE group was 12.8% ($p < .001$), the PEC was 9.5% ($p < .01$), the PC was 9.1% ($p < .01$), and the P group was a non-significant 3.8% below the initial values at the 1-year follow-up. Perhaps continued weight loss is best effected through continued in-therapy treatment, booster sessions à la Stuart, or a gradual phasing out of therapy with concomitant buildup of environmental supports.

Generalized Use of Behavioral Programs

Given the overall weight loss and the characteristics of our population (age, socioeconomic status, percent overweight), it does appear that we are able to generalize findings to a nonstudent population. Our subjects ranged in age from 16 to 62 years of age with a mean of 31.5 years. We observed no significant relationship between weight change and age or socioeconomic status, although admittedly the socioeconomic status range was limited.

Exercise

A major focus of this experiment was to evaluate the influence of exercise. A potential problem was our ability to convince subjects of varying ages and degrees of overweight to gradually increase their energy output from 150 to 400 kcalories above their basal levels. Data taken from exercise charts indicated that

the subjects averaged 91% of the required energy output. One might expect older and more obese subjects to have a more difficult time exercising, yet no such relationship was found. Many subjects commented that the gradual increase in exercise, starting at a low 150 kcalories per day, helped them get their previously inactive bodies in shape at a pace that was not too painful. In addition, as the exercise requirement was gradually increased, it gave them time to build up environmental supports for such activity (buying bikes, joining formal exercise programs, etc.). Graphing was viewed as helpful in visualizing progress over time. Also, therapists urged group members to form exercise cohorts among themselves. Finally, on two occasions, therapist models demonstrated appropriate exercises and levels of exertion.

Exercise Versus Contingency Management

This study also provided a contrast of exercise with contingency management whose efficacy has been previously demonstrated (Bellack, 1976; Mahoney, 1974). As previously noted, the main effects of exercise, contingency management, and the interactions were not significant. However, there was a tendency toward an effect for exercise at the 1-year follow-up with mean weight losses of 12.25 and 14.6 pounds (5.5 and 6.6 kg) for those exposed to contingency management and exercise, respectively. In general, this influence of exercise is consistent with the findings of Harris and Hallbauer (1973) and supports its further implementation in weight reduction programs.

Program Adherence

As previously noted, data on program adherence is sparse and limited to self-report questionnaires. Wollersheim (1970) reported differences in eating behavior but did not relate these data to weight loss. However, Mahoney (1974) did show a significant correlation between weight loss and the ability to eliminate inappropriate eating habits. Also, Bellack et al. (1974) found that one of nine program behaviors was significantly related to weight loss.

In contrast to these questionnaire data, we rated program adherence during weekly structured interviews. These data indicated that our subjects engaged in the required behaviors at a reasonably high level. However, as noted, of the 10 behaviors, only uncontrolled eating was significantly related to weight loss, and the combined influence of all behaviors accounted for a small and insignificant proportion of the weight loss variance.

These data on program adherence are somewhat perplexing. The combined effect of our scoring procedure and the response of the subjects provided little variation, which was corrected via transformed scores. Whether this transformation sufficiently enlarged the variation to achieve a significant relationship is mere speculation. If so, the data appear to undermine the presumed influence of the behavioral approach to weight loss. If subjects apply behavioral strategies and change their eating and activity patterns but these variables do not correlate with weight loss, then other so-called nonspecific factors may be operative.

Behavioral Interventions: A Social Influence Process?

The changes in eating and activity patterns may operate within a broader social influence framework to mediate weight loss. In this study, social influence variables were adequately controlled within the therapeutic context. Wollersheim's (1970) comparison of behavioral (focal), nonspecific, and social pressure groups also controlled for the influence of extraneous social variables during "in-therapy" time. However, a characteristic of behavioral approaches is the extremely large amount of "out-of-therapy" time requested of subjects. They record, graph, count, and monitor ad infinitum. These tasks require a great deal of time and activity in the change process.

This effort is unique to behavioral approaches and in marked contrast to other weight reduction regimens. For example, the performance of highly visible "out-of-session" behaviors (e.g., exercise) may increase social reinforcement for adherence well above that available for other less obvious weight reduction regimens such as drugs or diets. It may

well be that any procedure with a credible rationale, behavioral or otherwise, that engages subjects and continuously prompts their attention to weight loss will be effective.

A Longitudinal Study of the Personality Correlates of Marijuana Use

Edwin J. Kay, Arthur Lyons, William Newman,
Donald Mankin, and Roger C. Loeb
Lehigh University

Two hundred and fifty-one male students completed the California Psychological Inventory, the Adjective Check List, and a drug-use questionnaire in the fall of their freshman year and in each of one, two, or three succeeding springs. Three prevailing patterns of drug use were identified. *Continuous nonusers* never disclosed marijuana use; *switched nonusers* did not disclose marijuana use initially but did so on a later questionnaire, and *users* disclosed marijuana use both initially and later. Enduring differences between users and continuous nonusers were found. The switched nonusers generally had scores between those of the users and continuous nonusers. On several scales, switched nonusers were similar to users both before and after their use of marijuana. It is concluded that marijuana use, both present and future, can be predicted by a certain pattern of reported personality characteristics.

A number of investigators have compared users and nonusers of marijuana on a variety of psychosocial and personality measures. Several (Brill & Christie, 1974; McAree, Steffenhagen, & Zheutlin, 1972; Richek, Angle, McAdams, & D'Angelo, 1975) have found few or no significant differences between the two groups. In other cases (Grossman, Goldstein, & Eisenman, 1974; Zinberg & Weil, 1970), group differences have been found only when marijuana use was chronic. However, many researchers have reported significant differences between users and nonusers (Cunningham, Cunningham, & English, 1974; Fisher, 1974; Graham & Cross, 1975; Hogan, Mankin, Conway, & Fox, 1970; Jessor, Jessor, & Finney, 1973; McLaughlin, 1974; Simon, Primavera, Simon, & Orndoff, 1974). The great majority

of the studies cited above have used data collected at one testing only and thus do not show whether the personality differences sometimes found were antecedent or consequent to marijuana use. In addition, they could provide no information on the consistency of the measures over time and on the characteristics of individuals who change their patterns of drug use.

Two studies (Brill & Christie, 1974; Jessor et al., 1973) did contain a longitudinal design. Brill and Christie found only slight differences between users and nonusers and therefore did not report longitudinal data. In the Jessor et al. (1973) study, high school students were classified into one of three groups: nonusers of marijuana initially and a year later (NU-NU); nonusers of marijuana initially who became users of marijuana 1 year later (NU-U); and users initially and 1 year later (U). On a number of personality measures, the NU-U subjects initially fell between the NU-NU and U groups, differing significantly from NU-NU subjects on a number of dimensions. For the NU-NU subjects there were no significant changes over time. In contrast, for the NU-U subjects there were significant changes in which they became more similar to the U

This research was supported by National Institute of Mental Health Grant R01DA0054. We thank the anonymous reviewers for their valuable suggestions.

subjects on numerous measures. In summary, high school respondents who switched from nonuse to use of marijuana were initially between nonusers and users, and they became more like users over time. Jessor et al. also included a sample of college students in their study, but unfortunately they did not collect longitudinal data on these subjects.

The present study is a modified replication of Hogan et al. (1970) in that the subjects were from Lehigh University and some of the same personality measures were used. In that study, users and nonusers differed on such measures as socialization, flexibility, and empathy. The addition of a longitudinal design (similar to that of Jessor et al., 1973) makes it possible to assess the consistency of the reported differences in characteristics of users and nonusers over time and to check for personality characteristics and changes in nonusers who became users. Concurrent validity could also be evaluated, since more than one personality measure was used.

Method

Subjects

Each fall during the years 1971, 1972, 1973, 200 randomly chosen male freshmen entering Lehigh University were solicited for voluntary participation. The various groups of students were then contacted for follow-up studies in the spring following initial contact and for successive springs up to and including the spring of 1974. Thus, freshmen entering in the fall of 1971 were contacted then and in the springs of 1972, 1973, and 1974; freshmen entering in the fall of 1972 were contacted then and in the springs of 1973 and 1974; freshmen entering in the fall of 1973 were contacted then and in the spring of 1974. Initially, 130 (65%) of the 200 students who were contacted in the fall of 1971 agreed to be in the study; the corresponding numbers of freshmen entering in the fall of 1972 and 1973 were 124 (62%) and 112 (56%), respectively. The numbers of students participating in the initial testing and all follow-up testing were 68, 85, and 98 for the freshmen entering in the fall of 1971, 1972, and 1973, respectively. Each subject was paid for each testing session in which he participated.

The problem of subject loss is attributable to several factors. First, only students remaining at Lehigh for the duration of the research (1-3 years) were included in the final samples. Second, among students remaining at Lehigh, some could not be located during the testing weeks. And third, some students who were contacted were unwilling or unable to participate in all testing sessions. This resulted in the following percentages of original volunteers completing all testing sessions:

52% of those entering in 1971, 69% entering in 1972, and 87% entering in 1973. These figures are similar to other longitudinal research in the area (Brill & Christie, 1974; Jessor et al., 1973).

Procedure

For each test session, the subjects completed three instruments: a drug questionnaire (including demographic as well as drug use information); the Adjective Check List (ACL; Gough & Heilbrun, 1965); and the California Psychological Inventory (CPI; Gough, 1964). Subjects reported varying levels of marijuana use, and a small minority reported the use of other illegal drugs. The clearest distinction among subjects was whether or not any marijuana use was disclosed for a given test session.

Results

The analyses reported below are only for those subjects who participated in all of the appropriate testing sessions of the experiment. According to their responses on the various administrations of the drug questionnaire, the subjects were assigned to one of four categories. A subject was categorized as a *continuous non-user* (CNU) if he did not disclose use of marijuana on any administration of the drug questionnaire. A subject was categorized as a *user* (U) if he disclosed use of marijuana on the initial administration of the drug questionnaire. A subject was categorized as a *switched nonuser* (SNU) if he did not disclose marijuana use at the initial administration of the drug questionnaire but did disclose such use on some subsequent administration of the drug questionnaire. No subjects were found in the fourth possible category, *switched user* (disclosure of marijuana use on the initial administration of the drug questionnaire but denial of marijuana use on later questionnaires).

Replication of Hogan et al.

Our first aim was to see if our data replicated the study of Hogan et al. (1970), who administered the CPI to comparable subjects. Table 1 shows the raw score means on the CPI scales for U and CNU subjects for various administrations of the test. The data from the fall and first spring are for subjects who participated in the experiment for 1, 2, or 3 years; the data from the second spring are for those subjects who participated in the experiment for 2 or 3

years; and the data from the third spring are for those subjects who participated in the experiment for 3 years (i.e., those who entered Lehigh in 1971). If the four drug use categories of Hogan et al. (frequent users, occasional users, nonusers, and principled nonusers) are collapsed into two categories (users and non-users), then their Table 3 data can be compared with our fall data. The comparison indicates that the results of our initial fall testing closely replicated Hogan et al. Furthermore, the pattern of results endured over time as assessed by our three retests. Differences that both replicated Hogan et al. and endured over time occurred on six scales. Compared to CNU subjects, U subjects were significantly higher in Social Presence and Flexibility and lower on Responsibility, Socialization, Self-control, and Achievement via Conformance.

In Table 2, we present the mean CPI scores for all three categories of subjects on the six scales that consistently differentiated U and CNU subjects over time. SNU subjects generally fell between scores of U and CNU subjects. They were consistently similar to U subjects on the Social Presence scale and similar to CNU subjects in the Socialization, Self-control, and Achievement via Conformance scales. SNU subjects shifted on only one CPI scale; over time they came to resemble the U subjects on Flexibility.

Adjective Check List

The mean responses on the ACL by U and CNU subjects for various administrations of the test are presented in Table 3. Again the *t* test was used to compare the scale means for

Table 3
Mean Responses on the Adjective Check List Scales for User (U) and Continuous Nonuser (CNU) Subjects

Note. Asterisks indicate significant *t* tests between U and CNU means. Numbers in parentheses are *ns*.

* $p < .05$.

** $p < .01$.

U and CNU subjects. On the initial administration, U and CNU subjects differed significantly at the .01 level on 10 of the 25 scales; for one scale the difference was significant at the .05 level. Users were significantly higher than CNU subjects on Liability, Heterosexuality, Exhibition, and Change. CNU subjects were significantly higher than U subjects on Self-control, Personal Adjustment, Achievement, Endurance, Order, Autonomy, and Deference.

In examining Table 3, we see that the original differences on these 11 scales held up consistently over the 3 years of the study. In the spring of the third year, the magnitude of the differences was the same, although some differences were not statistically significant. Only subjects who entered school in the fall of 1971 were measured in the spring of the third year; this drop in sample size substantially reduced the power of the statistical test. Nonetheless, it is impressive that 2½ years after the first test, the direction of the differences remained the same.

The data for the 11 ACL scales for the SNU subjects as compared to U and CNU subjects are presented in Table 4. For the first two test

sessions, with only one exception (Personal Adjustment for first spring), SNU subjects fell between U and CNU subjects on these 11 scales. However, in the last two test sessions, this pattern did not occur. Thus, the differences among the three groups on the 11 scales changed over time. A careful examination of Table 4 reveals a fairly consistent pattern. Over time, many of the ACL scale scores of the SNU subjects become more like those of the U subjects. The shift from similarity with CNU subjects to similarity with U subjects is clear on the following scales: Socialization through Conformity, Liability, Autonomy, and Change. However, on the Order, Heterosexuality, and Exhibition scales, the SNU subjects were consistently similar to U subjects.

Finally, to assess concurrent validity, we hypothesized that the significant differences found between U and CNU subjects would be in the same direction for the CPI and the ACL when the two scales are positively correlated (Gough & Heilbrun, 1965) and in opposite directions when the two scales are negatively correlated. Fifty-eight of the 66 possible cases supported this hypothesis; that is, the CPI and ACL scores were in the predicted direction.

Table 4

Mean Scores of User (U), Switched Nonuser (SNU), and Continuous Nonuser (CNU) Subjects for Selected Adjective Check List Scales

Scale	Time of administration											
	Fall			1st spring			2nd spring			3rd spring		
	U (78)	SNU (58)	CNU (115)	U (78)	SNU (58)	CNU (115)	U (38)	SNU (47)	CNU (68)	U (12)	SNU (29)	CNU (27)

Exhibition	50.0	48.8	45.1**	51.7	50.3	45.7	51.4	52.9	47.6	50.5	56.9	44.6*
Autonomy	51.8	48.4	47.3	53.7**	49.6	47.6	53.4	54.0	48.1**	50.8	56.2	46.7*
Change	51.6*	46.6	45.3	53.6	48.0	46.5	52.6	48.8	46.7	54.2	54.0	44.4*
Deference	47.2	50.2	52.5	45.3**	49.1	51.9	47.2	45.5	52.2*	49.2	43.2	53.6*

Note. Asterisks next to scores indicate significant *t* tests when compared to SNU means. Numbers in parentheses are *ns*.

* $p < .05$.

** $p < .01$.

The probability of finding this amount of agreement by chance is extremely low ($p < .001$). Furthermore, on the correlations between CPI and ACL scores, 32 of the 58 correlations in agreement with our hypothesis were significant, whereas none of the 8 cases in disagreement with our hypothesis was significant.

Discussion

Comparing our data to those of Hogan et al. (1970), we are impressed that the personality correlates of marijuana use among the reputedly "straight," apathetic, job-oriented college youth of the early 1970s are strikingly similar to the personality correlates associated with marijuana use among the "hippie" activist college youth of the late 1960s. Although the present sample of college males at a relatively small and conservative university is not likely to be representative of American youth, the subjects are probably similar to a large number of college students. This successful replication of Hogan et al. provides support for the findings of both studies and implies that the personality patterns associated with marijuana use and nonuse have not changed significantly over the years.

The consistency between studies and the consistency across measures and across years (at least on the CPI) within our study suggests that certain people with specifiable personality patterns fall into our three categories of continued nonusers, users, and switched nonusers. The distinction between users and nonusers is clearest in three personality clusters. First, nonusers tend to be higher in several indices of what might be labeled *conformity*. On the CPI, nonusers had high scores on three of the group of scales described by Gough as "measures of socialization, maturity, responsibility, and intrapersonal structuring of values" (1964, p. 10). These three scales (Responsibility, Socialization, and Self-control) all reflect a concern with social standards. The low scores of the drug users reflect relative irresponsibility, rebelliousness, and hostility to rules and conventions compared to nonusers. It is interesting to note that even nonusers in our sample scored below Gough's (1964) male norms on two (Responsibility, Self-control) of the scales.

Conformity among nonusers is also reflected on the ACL scales of Deference, Order, and Self-control. On the other hand, the individuality and lack of conformity of the user is evidenced in high ACL scores on Autonomy, Change, Exhibition, and Liability.

The second distinguishing personality cluster is related to the issue of socialization and conformity. It is a set of characteristics that increases the likelihood of success through conventional means. Nonusers are relatively high in Achievement through Conformance on the CPI. This scale indicates efficiency, organization, and industriousness. Similarly, on the ACL, nonusers were higher on Achievement and Endurance (persistence). They also demonstrated a more positive attitude toward their place in society by their superior scores on Personal Adjustment.

The third cluster of traits involves adventure seeking. On the CPI, users evinced more spontaneity (measured by Social Presence) and adventuresomeness (Flexibility). Similarly, users appeared high on adventure (Heterosexuality) and seeking novelty (Change) according to the ACL.

In summary, nonusers appear to be well socialized. They conform to norms, respect authority, strive for traditional goals, and rarely act on impulse. Users show a strikingly different picture. They are nonconforming, independent, adventurous, and spontaneous. This pattern generally supports contemporary myths about college-age drug users and nonusers. It should be remembered that these data are based on self-report measures; that is, they tell us how the subjects perceive, or claim to perceive, themselves. Thus, marijuana users and nonusers may in part be reflecting social expectations. How their self-perceptions relate to others' perceptions or to reality (however it is defined) has not been assessed.

At any rate, that users and nonusers reliably report self-perceptions that sharply differ is both interesting and potentially useful. The usefulness of these data becomes clearer when we examine the third group, the switched nonusers. It is noteworthy that approximately 90% of the SNU subjects had switched to marijuana use by the second spring testing. Thus, the data in the last two testings reflect postmarijuana use personality characteristics.

In general, this group fell between the users and the continuous nonusers on the various personality scales; this outcome replicates the study by Jessor et al. (1973). If we are interested in predicting which nonusers have the greatest chance of becoming users, there are several CPI and ACL scales that appear to be useful. Specifically, if SNU subjects show certain personality characteristics similar to U subjects (and dissimilar to CNU subjects) both before and after their drug use, those characteristics can be used as predictors of future drug use. SNU subjects were consistently similar to U subjects on the Social Presence scale of the CPI and on the Order, Heterosexuality, and Exhibition scales of the ACL. The SNU group can thus be described as consistently similar to the U group in being outgoing, socially self-confident, and spontaneous. One might say that the "extraverted personality" is susceptible to the use of marijuana.

Several studies have reported findings that support the conclusion that marijuana users are extraverts. Hogan et al. (1970) described the marijuana user as high in social poise (though this was offset by an "assertive non-conformity"). According to Brill & Christie (1974), marijuana users reported themselves as higher in the tendency to seek stimulation. Simon et al. (1974) reported users to be low in deference and order. Graham and Cross (1975) found that users value feelings and experience over planning and logic, an interpersonal responsiveness that seems to characterize our switched nonusers.

On the other hand, SNU subjects shifted from similarity with CNU subjects to similarity with U subjects on the Flexibility scale of the CPI, and on the Socialization through Conformity, Lability, Autonomy, and Change scales of the ACL. This second cluster of personality traits involving nonconformity, lack of responsibility, and change is reflected in most of the literature on drug users (e.g., Cunningham et al., 1974; Grossman et al., 1974; Hogan et al., 1970; Simon et al., 1974; Zinberg & Weil, 1970). However, these studies only compared users with nonusers. Thus, the characteristics that SNU subjects shared with U subjects after they started using marijuana appear to be excellent post hoc discriminators;

they are not useful in discriminating nonusers who later become users from nonusers who continue not to use marijuana.

Two final points relate to the personality tests. First, contrary to the claims of some critics of the CPI, this longitudinal study found little evidence of shifts in personality results in conjunction with changes in drug use. Our SNU subjects changed on only one CPI scale—Flexibility. This supports our earlier contention that a certain personality type may be recruitable to marijuana use rather than the typical interpretation that marijuana use results in personality changes.

The second point is that in contrast to the consistency of the CPI scores, some ACL scores did shift among SNU subjects. On the ACL, SNU subjects demonstrated a trend over time toward similarity to users. As the ACL was developed to assess self-concept, this difference may imply that SNU subjects are experiencing and reporting changes in their self-concepts. Following their participation in marijuana use, the SNU subjects developed a self-concept of themselves similar to marijuana users. This change is not reflected in personality trait modifications as measured by the CPI. Perhaps such situational influences as drug use and associated environmental conditions have impact on ACL-type self-concept without resulting in changed perceptions of personality characteristics measured by the CPI.

The Child Behavior Profile: I. Boys Aged 6-11

Thomas M. Achenbach

National Institute of Mental Health, Bethesda, Maryland

The goal was to develop a descriptive classification system that could be used to group children for research and clinical purposes, to reflect adaptive competencies as well as behavior problems, and to facilitate quantitative assessment of behavioral change. The system is embodied in a series of Child Behavior Profiles that are standardized separately for children of each sex at ages 4-5, 6-11, and 12-16. The profiles are scored from the Child Behavior Checklist (CBCL), which was designed to obtain parents' reports of their children's competencies and problems in standardized format. This article reports standardization of the profile for boys aged 6-11. Factor analysis of the CBCLs of 450 disturbed boys yielded nine behavior problem scales labeled *Schizoid*, *Depressed*, *Uncommunicative*, *Obsessive-Compulsive*, *Somatic Complaints*, *Social Withdrawal*, *Hyperactive*, *Aggressive*, and *Delinquent*. The first five problem scales load on a second-order factor labeled *Internalizing*, and the last three load on a factor labeled *Externalizing*. Three social competence scales entitled *Activities*, *Social*, and *School* were also constructed from the CBCL. Norms are based on a normal sample of 300. Comparison of disturbed and normal boys showed differences ($p < .001$) on all behavior problem and social competence scores. Eight-day test-retest correlations averaged .89, whereas interparent correlations averaged .74. Computerized and hand-scored versions of the profile can be used to display item and scale scores for individual boys.

One of the greatest handicaps to research and communication on child psychopathology has been the lack of a standardized, objective, and reliable way of describing and classifying behavior disorders. Not until the 1968 edition of the American Psychiatric Association's *Diagnostic and Statistical Manual* (DSM; APA, 1968) was the need for a differentiated classification of children's disorders even recognized in the official nomenclature. Prior to the 1968 edition, the only childhood disorders recognized

by the DSM were adjustment reaction of childhood and childhood schizophrenia.

The author is indebted to the staffs of the many clinical agencies that have contributed to this work, as well as to Sue Fleisher for her unflagging efforts in all phases of the research, Melvin Lewis for his collaboration in developing the behavior problem component of the CBCL, and Brian McLaughlin and Craig Edelbrock for programming the Child Behavior Profile.

Requests for reprints, for copies of the CBCL, and for computerized and hand-scored versions of the Child Behavior Profile should be sent to Thomas M. Achenbach, Laboratory of Developmental Psychology, Building 15K, National Institute of Mental Health, 9000 Rockville Pike, Bethesda, Maryland 20014.

Although provisional guides to classification such as the DSM may be needed during the early stages of a field's development, the inadequacy of the DSM has inspired numerous attempts to evolve alternative methods of classification for childhood disorders. The most common approach has been to factor analyze checklists of behavior problems. However, the diversity of checklists, subject samples, sources of data, and methods of analysis has led to almost equally great diversity of results (Achenbach & Edelbrock, in press). One of the recurrent differences among studies is whether they yield a small number of broad-band factors or a larger number of narrow-band factors. The number and breadth of the factors has been determined largely by the number of items used and the methods of analysis. At one extreme, Quay and Peterson's (1967) 55-item Behavior Problem Checklist typically yields two broad-band factors labeled *Conduct Problem* and *Personality Problem*, although

two smaller factors labeled *Inadequacy-Immaturity* and *Socialized Delinquency* have also been found (cf. Quay, 1972). At the opposite extreme, Baker and Dreger (1973) have derived 30 factors from a checklist of 274 items.

Findings of a few broad factors and numerous narrower factors are not necessarily contradictory, as second-order analyses have shown narrow-band factors to be subsumed by broad groupings like the Conduct Problem and Personality Problem factors (Achenbach, 1966; Miller, 1967). Other analyses by Achenbach (1966) have shown that the two broad-band groupings—which he labeled *Externalizing* and *Internalizing*—were replicated in child psychiatric samples differing in age, sex, and socioeconomic status, but that the narrow-band factors differed among various subgroups. It thus appears that the broad-band factors represent general behavior patterns but may mask syndromes that vary with such characteristics as sex and developmental level.

The value of any classification system depends on the function it is to serve. In our present state of ignorance about etiology, prognosis, and appropriate treatment, the worth of a system for describing and classifying child psychopathology can be measured in terms of the following criteria: (a) It should provide a description of behavior in a standardized format that is useful to clinicians and researchers alike. (b) It should be differentiated enough to include narrow-band syndromes peculiar to particular subgroups. (c) It should not rest on clinical inferences by professionals, as few children in need of help receive adequate professional attention. (d) It should reflect children's positive adaptive competencies as well as their maladaptive characteristics. (e) It should enable us to group children for purposes of research on etiology, epidemiology, and treatment effectiveness. (f) It should facilitate quantitative assessment of behavioral change in order to evaluate prognosis under various conditions.

This article reports efforts to develop a descriptive classification system that will fulfill the six criteria just enumerated. Separate analyses are performed for children divided according to age and sex in order to detect patterns that may be peculiar to particular subgroups. Data are obtained with the Child

Behavior Checklist (CBCL), which comprises not only a diverse array of behavior problems but also items reflecting adaptive competencies, including participation in various activities, social relationships, and school success. These items form three social competence scales on which children are scored in relation to norms for their age and sex. The CBCL, which takes about 17 minutes to complete, is designed to be filled out by parents or parent surrogates, because they typically have a more comprehensive picture of their children's problems and competencies than do any other possible informants. Furthermore, parents' views and biases are pivotal in determining whether clinical services are obtained and which treatment options are implemented; they are also important in determining the long-term prognoses.

Data obtained with the CBCL are entered on the Child Behavior Profile, which displays the items reported by parents as well as the child's standing on narrow- and broad-band syndromes. Using either a computerized or a hand-scored version of the profile, the clinician or researcher can obtain an overview of the specific behavior reported by the parent, how the child's problems and competencies cluster, and how the child compares with normal children of similar age and sex. The profile approach preserves more information than does classification into mutually exclusive categories according to individual syndromes, and the profiles themselves can be used as a basis for multidimensional classification. The profile described here was constructed from data on normal and clinical samples of boys 6–11 years old. Subsequent articles will report the profiles for boys 4–5 and 12–16, and girls 4–5, 6–11, and 12–16.

Method

CBCL Behavior Problem Items

Development of the CBCL began with the behavior problem checklist that was constructed by Achenbach (1966) from a survey of existing literature and case histories of 1,000 child psychiatric patients. The original checklist was designed to be filled out from case history data by raters using present-absent response alternatives. It was adapted for parents' use by simplifying the wording, expanding the present-absent alternatives

to a 0-1-2 scale, and adding new items in consultation with clinicians. Pilot editions were further revised on the basis of item analyses and feedback from parents, clinicians, and paraprofessionals.

The current edition comprises 118 behavior problem items to which the parent responds by circling a 0, 1, or 2 according to the following instructions:

Below is a list of items that describe children. For each item that describes your child *now* or *within the past 12 months*, please circle the 2 if the item is *very true* or *often true* of your child. Circle the 1 if the item is *somewhat* or *sometimes true* of your child. If the item is *not true* of your child, circle the 0.

The items are intended to provide broad but non-redundant coverage of behavioral problems that can be rated with a minimum of inference. The parent is requested to write in descriptions of behaviors for items that might otherwise be ambiguous. For example, Item 28 is: Eats or drinks things that are not food (describe) _____. Parents' descriptions make it possible to discriminate between those who are concerned about their child's consumption of junk foods and those whose child is eating dirt, paint, and so on. Only nonfood substances such as the latter are scored on the Child Behavior Profile. In addition to the 118 items, spaces are provided for parents to write in unlisted physical problems having no known medical cause and any other problems that are not listed.

CBCL Social Competence Items

Following a survey of the meager existing literature on social competence indices for children, descriptions of positive behavioral characteristics were piloted in various formats with parents. It was found that items paralleling the behavior problems but describing positive characteristics inevitably sounded like lists of boy scout virtues with a strong social desirability component. Most parents endorsed all such items as describing their child. On the other hand, items of the type used on the Vineland Social Maturity Scale (Doll, 1965) failed to discriminate among children of normal intelligence. The items found to be most successful and ultimately selected for the CBCL comprise scales of involvement and attainment in the three areas described below.

Activities scale. This scale consists of scores for the amount and quality of the child's participation in (a) sports; (b) nonsports hobbies, activities, and games; and (c) jobs and chores. The parent is first asked to report the participant sports (up to three) that the child likes best. Beside each sport, the parent is asked to check boxes indicating how much time—compared to other children of the same age—the child spends in the sport and boxes indicating how well—compared to other children of the same age—the child does in each one. The alternatives include *don't know*, *below average*, *average*, and *above average*. A second item, with similar response alternatives, is provided for reporting the child's favorite hobbies, activities, and games, other than sports. On the third item of the Activities scale,

the parent is to list the child's jobs or chores (up to three). Beside each entry the parent is to check boxes indicating how well the child carries it out, compared to other children of the same age. The response alternatives are like those of the preceding items.

After trying other response formats, such as requesting parents to report the actual frequency of each activity, the present format was chosen for three reasons: (a) The significance of the frequency of participation varies greatly with the particular activity and environment. (e.g., Opportunities for riding bicycles are generally more frequent than for skiing, but both depend on the season of the year and the locality.) (b) To make the parent's task as easy as possible, we wished to use a format of maximum simplicity and generality. (c) Recognizing that we are obtaining the parent's perception of the child, we wished to maximize the power of the CBCL to discriminate children for whom parents could report at least some evidence of social competence from those for whom parents could report nothing positive.

The scoring system for the Activities scale allocates 0-2 points for number of sports, with 0 being assigned if one or no sport is listed, 1 point for two sports, and 2 points for three sports; 0-2 points for the mean score obtained for sports participation and skill, with 0 assigned for each response of *below average*, 1 for each response of *average*, 2 for each response of *above average*, and *don't know* responses omitted from scoring; 0-2 points for number of activities; 0-2 points for average amount and quality of participation in activities; 0-2 points for number of jobs and chores; and 0-2 points for average quality of job performance. The latter four scores follow the same scoring principles as outlined for sports.

The reason for assigning a score of 0 to a report of either zero or one sport, activity, or job is that so few parents of children in clinical samples reported no sports, other activities, or jobs that the difference between none and one did not appear worth recognizing in the scoring. However, a child who has none can receive only a 0 for participation and skill in that area, whereas a child who has one can receive up to 2 points for participation and skill for that one entry. The six scores for the Activities scale are added together to provide a summary score that can range from 0 to 12, and this is entered with its *T* score on the Child Behavior Profile, as explained later.

Social scale. The Social scale consists of scores for (a) the child's membership and participation in organizations; (b) number of friends and contacts with them; and (c) behavior with others and alone. On the first item, the parent is asked to list (up to three) organizations, clubs, teams, or groups the child belongs to and to indicate how active the child is in each, compared to other children of the same age. The number of organizations and amount of participation in each are scored 0-2 in the same fashion as items on the Activities scale. On the next item, the parent is to indicate how many close friends the child has, with the response alternatives being *none*, 1, 2 or 3, and 4 or more. *None* and 1 are both scored 0, 2 or 3 is scored 1, and 4 or more is scored 2. The parent is also asked to indicate how

many times a week the child does things with his/her friends. The responses—less than 1, 1 or 2, and 3 or more—are scored 0, 1, and 2, respectively.

The third item of the Social scale asks: "Compared to other children of his/her age, how well does your child: Get along with his/her brothers and sisters? Get along with other children? Behave with his/her parents? Play and work by himself/herself?" The response alternatives are *worse*, *about the same*, and *better*, and they are scored 0, 1, and 2, respectively. Responses to the first three questions are averaged to provide a score for behavior with others, whereas the response to the last question provides a score for independent behavior. The Social scale score is the sum of the six scores just described, each of which can range from 0 to 2, for a possible total of 12.

School scale. The School scale consists of scores for (a) the average of the child's performance in academic subjects; (b) placement in a regular or special class; (c) being promoted regularly or held back; and (d) the presence or absence of school problems. For academic performance, the alternatives are *failing*, *below average*, *average*, and *above average* for reading, writing, arithmetic, spelling, and/or other subjects. The response alternatives are scored 0, 1, 2, and 3, respectively, and are averaged to provide a score ranging from 0 to 3.

The parent is next asked to indicate whether the child is in a special class, and, if so, what kind; whether the child has ever repeated a grade, and, if so, the grade and reason; and to describe any academic or other problems the child has had in school. Negative answers to each of these items are scored 1, and answers indicating school difficulties are scored 0. These items thus provide three 0-1 scores, which, when added to the score for academic performance, yield a 0-6 score for the School scale.

Construction of the Child Behavior Profile

The behavior problem scales of the profile were derived through factor analysis of CBCLs filled out by parents of 450 boys being evaluated in 20 East Coast mental health settings. These included guidance clinics, health maintenance organizations, and private practices. Racial composition was 79.7% white, 18.7% black, and 1.6% other. Mean socioeconomic status (SES) was 4.4 ($SD = 1.8$) based on Hollingshead's (Note 1) 7-step scale for breadwinner's occupation. To ensure that younger and older boys contributed equally to the profile, the sample contained equal numbers of 6- to 8-year-olds and 9- to 11-year-olds, with approximately equal numbers at each year.

Norms for the profile were computed from CBCLs of 300 normal boys, 50 at each age from 6 to 11. These CBCLs were obtained by interviewers who went to randomly selected homes in the greater Washington, D.C., area, as described elsewhere (Achenbach & Edelbrock, Note 2). The normative sample contained no boys who had received mental health services in the previous year. Racial composition was 79.4% white, 18.3% black, and 2.3% other. Mean SES was 4.1 ($SD = 1.7$).

Results

Behavior Problem Scales

The frequency with which parents endorsed each item (i.e., scored it 1 or 2) was first tabulated to identify items that were too rare or common to add to the discriminative power of factor-based scales. With a lower cutoff of 5% and an upper cutoff of 95%, four items were found to be too rare and none was too common for inclusion in the factor analysis. The four low frequency items were: Item 75. Sexual problems (describe) ____; Item 78. Smears or plays with bowel movements; Item 105. Uses alcohol or drugs (describe) ____; and Item 110. Wishes to be of opposite sex. The low frequency for Items 73 and 110 does not mean that no sexual items remained for analysis (e.g., Item 5. Behaves like opposite sex; Item 59. Plays with own sex parts in public; Item 60. Plays with own sex parts too much; and Item 96. Thinks about sex too much) were all reported for at least 5% of the cases).

Narrow-band scales. A principal components analysis was performed on the 114 items meeting the 5% criterion for the 450 subjects. Because there is no unique criterion for rotation to simple structure, orthogonal (varimax) and oblique (direct quartimin) rotations were both performed on varying numbers of factors to identify the most robust. When more than 13 factors were rotated, factors that had consistently appeared in smaller rotations began to break down into factors having only two or three large loadings. When less than 11 factors were rotated, substantial groupings that occurred in the 11-, 12-, and 13-factor rotations were combined into very large factors. The 12-factor varimax rotation was selected as containing the best representation of the factors that appeared most consistently in the various rotations. However, only the largest 9 of the 12 factors were retained for the profile, as the smallest 3 had only 3-5 items with loadings $\geq .30$. Each of the 9 factors had at least 8 items with loadings $\geq .30$. Because the largest rotated factor (*Aggressive*) had 33 items with loadings $\geq .30$, and many of the items with loadings between .30 and .40 also had substantial loadings on other factors, only the items with loadings $\geq .40$ on this factor

Table 1

First-Order Varimax Loadings on Behavior Problem Scales

Internalizing scales		IV. Obsessive-Compulsive (cont.)	VIII. Aggressive (cont.)
<i>I. Schizoid</i>		93. Excess talk .34	68. Screams
40. Auditory hallucination .55		47. Nightmares .33	90. Swears
70. Visual hallucination .50		50. Anxious .33	25. Poor peer relations
29. Fears .44		Eigenvalue 4.03	88. Sulks
30. Fears school .41		<i>V. Somatic Complaints</i>	7. Brags
11. Clings to adults .37		56f. Stomach problems .64	43. Lies, cheats
50. Anxious .36		56a. Pains .50	27. Jealous
47. Nightmares .31		56b. Headaches .58	87. Moody
59. Public masturbation .30		56c. Nausea .56	19. Demands attention
75. Shy, timid .30		56g. Vomits .44	93. Excess talk
Eigenvalue 2.53		49. Constipated .41	48. Unliked
<i>II. Depressed</i>		51. Dizziness .39	Eigenvalue
35. Feels worthless .68		77. Sleeps much .32	<i>IX. Delinquent</i>
52. Feels guilty .67		54. Overtired .31	82. Steals outside home
32. Needs to be perfect .58		Eigenvalue 3.08	81. Steals at home
33. Feels unloved .55		<i>Mixed scale</i>	21. Destroys things belong-
112. Worrying .52		<i>VI. Social Withdrawal</i>	ing to others
103. Sad .51		48. Unliked .59	106. Vandalism
31. Fears own impulses .48		25. Poor peer relations .59	72. Sets fires
91. Suicidal talk .46		111. Withdrawn .56	101. Truant
12. Lonely .40		42. Likes to be alone .46	67. Runs away
14. Cries much .39		38. Is teased .36	39. Bad friends
50. Anxious .39		64. Prefers younger children .33	43. Lies, cheats
71. Self-conscious .39		34. Feels persecuted .32	20. Destroys own things
34. Feels persecuted .34		102. Slow moving .31	90. Swears
88. Sulks .32		Eigenvalue 3.05	23. Disobedient at school
45. Nervous .31		<i>Externalizing scales</i>	Eigenvalue
89. Suspicious .30		<i>VII. Hyperactive</i>	<i>Other Problems</i>
18. Harms self .30		8. Can't concentrate .65	2. Allergy
Eigenvalue 4.94		1. Acts too young .58	4. Asthma
<i>III. Uncommunicative</i>		61. Poor school work .56	5. Acts like opposite sex
65. Won't talk .61		62. Clumsy .48	6. Encopresis
69. Secretive .50		13. Confused .45	15. Cruel to animals
75. Shy, timid .42		17. Daydreams .43	24. Doesn't eat well
103. Sad .36		41. Impulsive .40	26. Lacks guilt
80. Stares blankly .33		64. Prefers younger children .40	28. Eats nonfood
71. Self-conscious .32		10. Hyperactive .36	36. Accident prone
13. Confused .32		79. Speech problem .31	44. Bites nails
86. Stubborn .30		20. Destroys own things .30	53. Overeats
Eigenvalue 2.97		Eigenvalue 3.75	55. Overweight
<i>IV. Obsessive-Compulsive</i>		<i>VIII. Aggressive</i>	56d. Eye problems
85. Strange ideas .52		3. Argues .71	56e. Rashes
100. Can't sleep .52		22. Disobedient at home .66	58. Picking
76. Sleeps little .45		95. Temper tantrums .64	60. Excess masturbation
84. Strange behavior .43		86. Stubborn .63	63. Prefers older children
9. Obsessions .42		37. Fighting .61	73. Sex problems
92. Walks, talks in sleep .40		16. Cruel to others .60	78. Smears feces
80. Stares blankly .40		97. Threatens people .57	96. Sex preoccupation
17. Daydreams .38		94. Teases .56	98. Thumb sucking
46. Twitches .37		74. Shows off .55	99. Too neat
83. Hoarding .37		104. Loud .51	105. Alcohol, drugs
66. Compulsions .36		23. Disobedient at school .51	107. Wets self
54. Overtired .36		57. Attacks people .50	108. Wets bed
13. Confused .35			109. Whining
			110. Wishes to be opposite sex

Note. Items are designated with the numbers they bear on the Child Behavior Checklist (CBCL) and summary labels for their content. For actual wording of items, see the CBCL. Other Problems items were excluded from scales because of low frequency or low loadings.

were retained for the scale constructed from the factor. Each of the scales constructed from the other 8 factors consisted of the items having loadings $\geq .30$ on those factors. The items, their varimax loadings, eigenvalues, and descriptive labels for each scale are presented in Table 1.

Scoring of scales. Because equal weights for items are likely to provide greater robustness in a linear discrimination system than are weights based on factor loadings (Wainer, 1976), the unweighted raw scores (0, 1, or 2) for all items of a scale were summed to obtain the subject's total score on the scale. The raw scores obtained by the 300 normal boys were used to compute normalized T scores for each of the nine scales. A T score of 80 was assigned to the highest raw score in the normal sample for each scale, excluding outliers. Because a substantial number of clinical subjects obtained higher raw scores than any normal subject on each scale, T scores up to 90 were added to the T scores based on the normal sample. This was done by dividing the T scores from 80 to 90 into as many intervals as there were raw scores between the highest score obtained by a normal subject and the highest raw score obtainable on the scale. These fractional T scores were then assigned to the raw scores from the highest score in the normal sample to the highest possible score and were rounded to the nearest whole T score.

Second-order analysis. The normalized T scores obtained by the clinical sample on the nine scales were intercorrelated and subjected to a principal components analysis, with varimax and direct quartimin rotations of the two factors having eigenvalues > 1.00 . The results of the two rotations were very similar in that Scales 1-5 (Table 1) all had loadings $\geq .63$ on the first second-order factor, whereas Scales 7-9 had loadings $\geq .65$ on the other second-order factor. There was a small difference in the ordering of the scales in that Scale 4 had a slightly higher loading than Scale 5 in the varimax rotation, whereas this order was reversed in the quartimin rotation. Scale 6 had moderate loadings on both factors in both rotations; they were .38 and .44 on the two factors of the quartimin rotation and .44 and .51 on the two factors of the varimax rotation. Because the scoring of some items on

more than one scale might inflate the correlations among scales, the second-order analysis was repeated on first-order scales from which all redundantly scored items were deleted. This yielded the same two second-order factors.

The ordering of the scales in Table 1 follows the order of their loadings on the second-order varimax factors, with Scale I having the highest loading on the first second-order factor, Scale VI having moderate loadings on both second-order factors, and Scales VII-IX having progressively higher loadings on the second second-order factor. The items of Scales I-V clearly form a broad-band grouping like the Personality Problem and Internalizing groupings found previously, whereas the items on Scales VII-IX form a broad-band grouping like the Conduct Problem and Externalizing groupings found previously (Achenbach, 1966; Miller, 1967; Quay & Peterson, 1967).

To obtain normalized T scores for Internalizing and Externalizing, raw scores were computed for each normal subject by summing his scores on all items of the five Internalizing scales and all items of the three Externalizing scales. Items that were included on more than one scale were scored only once to obtain the Internalizing or Externalizing score, but the three items that appeared on at least one Internalizing and one Externalizing scale were counted once each toward both the Internalizing and Externalizing scores. Normalized T scores were derived from the distributions of raw scores for Internalizing and Externalizing in the same way as for the nine first-order scales, with the following modification: Because the range of possible Internalizing and Externalizing scores extended far above the highest score obtained by any of the 450 clinical subjects, the highest raw score actually obtained by any clinical subject was assigned a T score of 89 and all higher possible raw scores were assigned a T score of 90. The T scores from 80 to 89 were assigned by dividing these T scores into as many intervals as there were raw scores from the highest normal (excluding outliers) to the highest clinical subject. These fractional T scores were assigned in sequence to the raw scores ranging from the highest score obtained by a normal subject to the highest score obtained by a

clinical subject. The fractional T scores were then rounded to the nearest whole T score.

Social Competence Scales

The scores obtained on the social competence scales by the 300 normal subjects were used to obtain normalized T scores. A T score of 20 was assigned to the lowest raw score obtained by a normal subject, excluding outliers. Because some clinical subjects obtained lower scores than any normal subjects on these scales, T scores between 10 and 20 were assigned by dividing them into as many intervals as there were raw scores between the score assigned a T score of 20 and the lowest raw score obtainable on the scale.

Age, SES, and Clinical Versus Normal Comparisons

To assess differences in scores related to age, SES, and clinical status, unweighted-means analyses of variance (ANOVAs) were performed on the 300 normal subjects and 300 of the clinical subjects, 50 at each age. SES was divided into three levels, comprising Hollingshead Occupational Categories 1 and 2, 3 and 4 and 5-7. Age was divided into two levels, years 6-8 and 9-11.

Behavior problem scales. A 3 (SES) \times 2 (age) \times 2 (clinical vs. normal) \times 9 (repeated measures on behavior problem scales) ANOVA showed significantly higher scores for clinical than normal subjects, $F(1, 588) = 517.73$, $p < .001$. SES was also significant, with upper-SES subjects obtaining the lowest scores and lower-SES subjects obtaining the highest, $F(2, 588) = 3.37$, $p < .05$. Age showed no effect ($F = .09$), and there were no significant interactions among SES, age, and clinical status. The repeated measures effect of scale was significant, $F(8, 4704) = 8.64$, $p < .001$, as were the interactions of scale with age, $F(8, 4704) = 2.39$, $p < .05$, with clinical status, $F(8, 4704) = 32.61$, $p < .001$, and with age and clinical status together, $F(8, 4704) = 2.33$, $p < .05$.

To elucidate these effects, a 3 (SES) \times 2 (age) \times 2 (clinical status) ANOVA was performed on each scale, with consideration being given only to differences that were reflected in

significant F values for the overall repeated measures ANOVA. All nine of the smaller ANOVAs showed higher scores for clinical than normal subjects, with $F(1, 588)$ values ranging from 67.97 to 408.29, all $ps < .001$. SES was significant for Somatic Complaints, $F(2, 588) = 3.88$, $p < .05$; Hyperactive, $F(2, 588) = 4.44$, $p < .05$; Aggressive, $F(2, 588) = 3.45$, $p < .05$; and Delinquent, $F(2, 588) = 5.43$, $p < .01$. In all significant comparisons, lower-SES subjects had the highest scores and upper-SES the lowest. Modified least significant difference contrasts (Winer, 1971) showed significantly higher scores for lower- than upper-SES subjects on all four scales and significantly higher scores for lower- than middle-SES subjects on the Delinquency scale.

The ANOVA for the Schizoid scale showed significantly higher scores for younger than older boys, $F(1, 588) = 6.33$, $p < .05$, but the lack of significant main effects for age in the other eight ANOVAs and the very small F of .09 for age in the repeated measures ANOVA indicates that age differences were minimal. Significant interactions between age and clinical status in the ANOVAs for the Depressed and Social Withdrawal scales both reflected higher scores for older clinical subjects than younger clinical subjects and lower scores for older normals than younger normals. However, on both scales, clinical subjects of both age groups scored significantly higher than normals. Table 2 presents all the mean scores, collapsed over age to save space.

Internalizing, Externalizing, and total score. Separate 3 (SES) \times 2 (age) \times 2 (clinical status) ANOVAs on Internalizing, Externalizing, and total raw score all showed significantly higher scores for clinical than normal subjects, with $F(1, 588)$ values ranging from 362.47 to 479.76, $ps < .001$. The SES effect was also significant for Externalizing, $F(2, 588) = 3.57$, $p < .05$, and for total score, $F(2, 588) = 4.63$, $p < .01$. In both cases, contrasts showed significantly higher scores for lower-SES than upper-SES boys. No other effects were significant in any of the ANOVAs.

Social competence scales. In a 3 (SES) \times 2 (age) \times 2 (clinical status) \times 3 (repeated measures on social competence scales) ANOVA, clinical subjects had significantly lower scores than normals, $F(1, 528) = 254.78$, $p < .001$.

Table 2
Mean Scores for Clinical and Normal Boys on Scales of the Child Behavior Profile

Scale	Upper SES		Middle SES		Lower SES	
	Clinical (63)	Normal (67)	Clinical (141)	Normal (97)	Clinical (96)	Normal (136)
Social Competence						
Activities	48.2	53.4	45.6	52.9	43.3	49.1
Social	42.1	55.4	39.1	51.9	40.0	50.0
School	43.0	60.1	41.2	57.8	38.2	52.3
Behavior Problems						
Schizoid	62.4	55.7	64.3	53.5	63.3	54.0
Depressed	63.8	52.9	66.1	52.4	67.4	52.5
Uncommunicative	65.0	52.6	67.0	53.1	68.2	53.5
Obsessive-Compulsive	62.5	52.3	64.9	52.4	67.0	53.2
Somatic Complaints	61.0	56.4	62.3	55.9	61.4	57.0
Social Withdrawal	64.5	54.2	65.7	53.7	66.9	53.7
Hyperactive	66.0	50.5	67.4	52.8	68.7	53.5
Aggressive	64.3	51.9	68.2	50.6	70.6	51.5
Delinquent	66.1	54.9	68.1	54.5	69.4	56.6
Internalizing	64.6	51.1	67.2	50.7	68.8	51.4
Externalizing	66.7	50.8	69.3	50.4	71.4	51.6
Total raw score	54.0	20.4	61.8	20.9	65.6	22.8

Note. Numbers in parentheses are *ns*. SES = socioeconomic status. All scores except total raw score are normalized *T* scores. Differences between clinical and normal samples are all significant at $p < .001$. See text for tests of SES differences.

(The total number of cases was less than in the behavior problem ANOVAs because some of the youngest subjects had insufficient school data to be scored on the school scale.) SES was also significant, with lower-SES subjects having the lowest scores and upper-SES subjects the highest scores, $F(2, 528) = 14.61$, $p < .001$. Age differences were not significant ($F = 1.68$), nor were any of the interactions among non-repeated measures dimensions. The repeated measures dimension was significant, $F(2, 1056) = 8.65$, $p < .001$, as were the interactions of scale with age, $F(2, 1056) = 3.09$, $p < .05$, and with clinical status, $F(2, 1056) = 27.83$, $p < .001$.

SES \times Age \times Clinical Status ANOVAs on each of the three social competence scales showed significantly lower scores for clinical subjects than normal subjects on all three scales, with $F_s(1, 528)$ ranging from 42.36 to 179.47, all $p_s < .001$. SES differences were also significant on all three, with $F_s(2, 528)$ ranging from 4.74 to 9.71, all $p_s < .01$. Contrasts showed significantly higher scores for upper-SES than lower-SES subjects on all three

scales and higher scores for upper-SES than middle-SES subjects on the Social scale. Middle-SES subjects scored significantly higher than lower-SES subjects on the Activities and School scales. The only other significant effect reflected higher scores by older than younger subjects on the Social scale $F(1, 528) = 4.73$, $p < .05$.

Format of the Child Behavior Profile

On the computer-scored version of the profile, face sheets describe the nature and purpose of the profile and provide a listing of items on each behavior problem scale, plus items not appearing on any scale. The printout for the behavior problem scales presents a graphic display in which raw scores for the scales are listed in nine columns, percentiles are listed to the left, and *T* scores are listed to the right. An asterisk designates the child's raw score in each column of the display, and the asterisks can be connected by pencil to provide a visual profile. Below the graphic display are printed abbreviations of the items reported by the

parent on each scale, together with the score (1 or 2) given each item by the parent, and the child's raw score and *T* score for each scale. To the right of the nine scales are printed any items scored as present but not belonging to a scale. Also printed are the total number of items scored as present and the sum of 1s and 2s for all items, for the Internalizing items, and for the Externalizing items, plus the *T* scores for Internalizing and Externalizing. The social competence scales are presented in similar fashion on another page. The hand-scored version of the profile is like the computerized version, except that all items are printed and the scorer enters and sums the scores obtained.

Test-Retest Reliability

An interviewer obtained CBCLs from mothers of 12 normal boys on two occasions at a mean interval of 8 days (range = 7-12 days). Pearson correlation coefficients on the 12 scales, Internalizing, Externalizing, and total behavior problem scores ranged from .72 for the Activities scale to .97 for total score (all $ps < .01$), with a mean of .89. (All means of correlations were computed by *z* transformation.) Dependent *t* tests for which *p* values were multiplied by 15 to correct for the number of comparisons (Winer, 1971) showed one significant difference from Time 1 to Time 2, a drop in total behavior problem score, $t(11) = 3.81$, $p < .05$. Even though this was the only significant change in means, it should be noted that 14 of the 15 means decreased, whereas only the mean for Delinquent Behavior increased from Time 1 to Time 2 ($p < .01$ for the proportion of decreases/increases by sign test). There thus appears to be a general tendency to report fewer behavior problems and fewer items indicative of competence on the second occasion, although the differences in most scores were slight.

To assess the short-term stability of profile shapes, a *Q* correlation was computed between each boy's Time 1 profile and his Time 2 profile. This was done by standardizing each of the 12 scale scores within the sample and computing a Pearson correlation coefficient between each boy's 12 scale scores at Time 1 and his 12 scores at Time 2. The mean of the 12 correlations on 12 variables was .86, which

is significant at $p < .001$ whether it is treated as a correlation on 12 observations or as 12 subjects \times 12 scores = 144 observations. To determine whether the correlation could be an artifact of the *Q* approach, a baseline correlation was obtained by pairing each boy's Time 1 profile with every other boy's Time 2 profile except his own. The mean of these 66 correlations was $-.04$, which indicates that the mean correlation of .86 between each boy's Time 1 profile and his own Time 2 profile was not an artifact of the *Q* approach. For workers interested in using the nine behavior problem scales alone, it may be useful to know that the mean *Q* correlation between Time 1 and Time 2 9-scale profiles was .84, whereas between random pairs it was .02. As a measure more sensitive to the similarity between profile elevations, the mean of Cattell's (1949) r_p was .78 between Time 1 and Time 2 12-scale profiles and .74 between the 9-scale profiles. For randomly paired Time 1 and Time 2 profiles, the 12- and 9-scale means were .01 and .02, respectively.

Interparent Agreement

Mothers and fathers of 37 clinic boys independently filled out the CBCL. Pearson correlations between scores obtained from mothers' and fathers' CBCLs on the 12 profile scales, Internalizing, Externalizing, and total behavior problem score ranged from .58 for the Activities scale to .87 for the School scale (all $ps < .001$), with a mean of .74. Dependent *t* tests for which *p* values were multiplied by 15 to correct for chance showed a significant interparent difference only on the School scale, where fathers gave higher scores than mothers, $t(36) = 3.38$, $p < .05$. Across all 15 comparisons, the fathers' mean scores were higher on six and the mothers' on nine ($p > .40$ by sign test).

After standardization of scores on each scale within the sample of 37, the mean *Q* correlation for the 37 pairs of 12-scale profiles was .69. For the nine behavior problem scales, the average *Q* correlation was .74. By comparison, the means of the 666 12- and 9-scale correlations for randomly paired mothers and fathers were $-.02$ and $.04$, respectively. The mean r_p for the wife-husband 12-scale profile pairs was .59 and for the 9-scale profile pairs was .69, com-

pared to .03 and .04, respectively, for the random pairs.

Long-term Stability of Behavior Problem Scores

As part of a follow-up study, 46 parents who had filled out the behavior problem portion of the CBCL when applying to child guidance clinics were asked to complete it again at a mean interval of 14.8 months (range = 9-27 months). The families had received a mean of 11.9 clinical interviews (range = 0-50), but all had terminated with the clinics before the follow-up was begun. To avoid overlap between the initial and follow-up data, the parents were asked to report only behavior problems occurring within the 6 months prior to follow-up, rather than within the previous 12 months, as requested on the initial CBCL. Because of this shorter baseline period, possible regression of scores toward the mean, and "hello/good-bye" effects, changes in scores should not necessarily be interpreted as indicating improvement.

Pearson correlations for the nine scales, Internalizing, Externalizing, and total score ranged from .26 for Somatic Complaints to .79 for Delinquent Behavior, with a mean of .63, all significant except Somatic Complaints. However, the follow-up CBCLs showed decreases on all nine behavior problem scales, as well as on total behavior problem score and *T* scores for Externalizing and Internalizing. With *p* values multiplied by 12 to correct for chance, the decreases were significant by dependent *t* tests for all scores except Schizoid, Somatic Complaints, and Social Withdrawal. The general decrease in reported problems was also reflected in the mean r_p of .43 between intake and follow-up profiles, compared with a mean r_p of .03 between the 1,035 randomly paired intake and follow-up profiles. Despite the decreases in reported problems, the mean *Q* correlation between initial and follow-up *T* scores was .64, indicating considerable long-term stability in profile shape, as compared to the mean *Q* correlation of .02 for the 1,035 random pairs.

Discussion

Although no other studies have taken precisely the same approach, comparison of

the present findings with the most similar previous studies, those of Achenbach (1966) and Miller (1967), reveals considerable similarity along with some differences that are worth noting. (A more extensive survey of previous findings for both sexes, various age groups, and various sources of data is presented by Achenbach & Edelbrock, in press.) Despite the differences in behavior checklists and the fact that Achenbach (1966) used case history data, six of the present narrow-band factors are similar to factors that he obtained for boys. These six are the Schizoid, Obsessive-Compulsive, Somatic Complaints, Hyperactive, Aggressive, and Delinquent factors. The last four of these six are also similar to narrow-band factors found by Miller (1967), which he named Anxiety, Hyperactivity, Infantile Aggression, and Antisocial. In addition, the Social Withdrawal factor found in the present study is similar to Miller's factor of the same name. Miller's failure to find factors like the Schizoid and Obsessive-Compulsive factors is probably due, as Miller pointed out, to the lack of severely disturbed children in his sample.

The remaining two narrow-band factors in the present study, those labeled Depressed and Uncommunicative, have no direct counterparts in the previous factor analyses of boys' behavior problems. However, the Depressed factor is quite similar to the Depressive Symptoms factor that Achenbach (1966) obtained for girls. The emergence of such a factor for boys suggests that cultural changes may be leading either to a greater incidence of depression in boys or to a greater willingness to acknowledge such feelings in boys. Whatever the reason, it appears that the recent spurt of interest in childhood depression is well justified (e.g., Lewis & Lewis, Note 3). The other narrow-band factor, labeled *Uncommunicative*, has no clear counterpart in either of the previous studies. Although the value of each scale lies less in the interpretation of its meaning than in its ability to add discriminative power to the profile as a whole, this scale is suggestive of a constriction in self-expression that might accompany depression in some children.

The second-order Externalizing and Internalizing factors are quite similar to the group-

ings given these names by Achenbach (1966) and to the second-order Aggression and Social Inhibition factors found by Miller (1967). Miller's remaining second-order factor, entitled *Learning Disabilities*, was not likely to appear in the present data because of the different approach taken to the scoring of school performance. Miller's inclusion of several similar items reflecting poor school performance (e.g., reads poorly; spells poorly; writes poorly) made a factor comprising these items almost inevitable. To avoid factors resulting from redundancy in items, the CBCL includes only the general item, *poor school work*, as a behavior problem. However, to provide a differentiated picture of school performance, the CBCL assigns scores for all academic subjects, which are then averaged and combined with scores for special versus regular class status, repeating grades, and other school problems to yield a score for the School scale.

The major objective of this research does not, of course, end with the creation of scales for behavioral problems and competencies. More important is the value of the profile for describing children's behavior in an economical but comprehensive and meaningful fashion, the power of the profile to discriminate among children who may benefit from different kinds of help, and the sensitivity of the profile to changes as well as stabilities in children's behavior. Because they preserve a maximum of information about children's behavior, the profile patterns may provide a much better basis for classifying children than do traditional diagnostic categories or scores on individual scales. The short- and long-term test-retest correlations indicate stability in patterning, and the interparent correlations reflect agreement between parents' perceptions of patterning in their children's behavior. Highly significant differences between normal and clinical subjects on all scales also demonstrate discriminative validity. Studies are now under way to determine whether profile patterns can be identified that significantly differ-

entiate children with respect to long-term prognosis and other clinically relevant characteristics.

Increasing the Interpersonal Problem-Solving Skills of an Alcoholic Population

James C. Intagliata

Division of Community Psychiatry, State University of New York at Buffalo

Sixty-four male alcoholics admitted into the Alcoholism Treatment Program at the Veterans Administration Hospital in Buffalo, New York, were assigned to either the control or treatment group. Control subjects participated in all standard treatment aspects of the program. Treatment subjects, however, participated in an additional 10 sessions of group therapy structured specifically to improve interpersonal problem-solving thinking skills. Comparisons conducted at the point of discharge (generally 6 weeks after admission) demonstrated that treatment subjects had made significantly greater improvement on a measure of problem-solving thinking than had controls. Further, a comparison of subjects' responses in a structured discharge interview demonstrated that treatment subjects were significantly more likely to anticipate and plan ahead for postdischarge problems than were control subjects. Analysis of the data in the study also revealed that the means-ends problem-solving procedure can reliably discriminate individuals within an adult alcoholic population who differ in their levels of social competence and in the quality of their planning for coping with postdischarge problems. Finally, follow-up at the 1-month postdischarge point indicated that the majority of treatment subjects contacted had made practical use of the problem-solving principles that were taught in the group sessions.

It has been suggested that the capacity to problem solve in real-life situations is one criterion for defining positive mental health (Jahoda, 1958). This suggestion has received increasing empirical support from a number of studies examining the relationship between cognitive interpersonal problem-solving skills and psychological adjustment. These studies have used the means-ends problem solving (MEPS) procedure (Platt & Spivack, 1975) to examine interpersonal problem-solving cog-

nition in a variety of groups including preschool age children (Shure, Spivack, & Jaeger, 1971; Shure, Newman, & Silver, Note 1), young adolescents (Platt, Spivack, Altman, Altman, & Peizer, 1974; Spivack & Levine, 1963), and adults (Platt, Scura, & Hannon, 1973; Platt & Spivack, 1972a; Platt, Spivack, & Siegel, 1975). The results have demonstrated that for each of the age categories, problem-solving cognition is an adaptive thinking ability that successfully discriminates between groups that clearly differ in their level of demonstrated adjustment (e.g., impulsive adolescents at a residential school vs. normal high school controls; adult psychiatric patients vs. normal adult controls). While these studies have demonstrated that problem-solving cognition can discriminate between groups that differ grossly in their level of adjustment, there is evidence that this variable can also discriminate among persons in a homogeneous group who differ only in the degree of their social competence or effectiveness (Platt & Spivack, 1972b; Ziegler & Phillips, 1962). Thus, empirical

This article is based on the author's doctoral dissertation, supervised by Murray Levine and submitted to the Department of Psychology at the State University of New York at Buffalo.

The author wishes to express his appreciation to the entire staff of the Alcoholism Treatment Unit 4-D of the Buffalo, New York, Veterans Administration Hospital for their assistance in conducting this study, and to Louis English who made valuable suggestions with respect to the analysis of study data.

Requests for reprints should be sent to James Intagliata, Division of Community Psychiatry, 462 Grider Street, Buffalo, New York 14215.

research has built a case for the assertion that interpersonal problem-solving cognition plays an important role in healthy human functioning.

The evidence that interpersonal problem-solving skill is intimately related to behavioral adjustment has quite naturally stimulated the development of intervention strategies designed to increase the problem-solving effectiveness of groups deficient in this ability. One of the most ambitious and successful strategies used has been Spivack and Shure's (1973) 12-week problem-solving skills training program for primary-grade children. The goal of this program was to teach children a style of problem solving that could guide them to cope more successfully with everyday problems. Results demonstrated that children who received the training, when compared with controls, showed generation of more alternatives to problems, better consequential thought, and a decided shift away from aggressive solutions to problems. Behaviorally, the trained children showed greater concern for the feelings of other children, were better liked by their peers (i.e., were sought out more), showed greater initiative in the classroom, and had greater autonomy (ability to complete activities and overcome obstacles without adult assistance).

Following these results, several attempts were made to modify this training approach so that it could be extended for use with adult populations that were deficient in interpersonal problem-solving skills. For example, Siegel and Spivack (1973) designed a program to train chronic schizophrenics in interpersonal problem-solving processes. Although they only piloted the program with 11 subjects, the authors were encouraged by the patients' responses and concluded that the approach seemed generally feasible. Platt (Note 2) reported on the use of a problem-solving skills training program with incarcerated heroin addicts. Though subjects were not randomly assigned to groups, the authors felt that the findings, which included a significant relationship between graduating from the cognitive problem-solving skills training program and successful parole performance, suggested both the feasibility and potential effectiveness of their intervention approach.

The present article reports the results of an extensive two-part study designed to extend training in cognitive interpersonal problem solving to an adult alcoholic population. The first study explores the interrelationships in this population between scores on the MEP procedure and (a) the Ziegler-Phillips (1962) social competence scores, (b) scaled vocabulary subtest scores from the Wechsler Adult Intelligence Scale (WAIS), and (c) scores on a discharge interview structured to assess the patient's anticipation of and planning for post-discharge problems. The second study assesses the impact of a 10-session cognitive problem-solving skills training program on subjects' problem-solving thinking and behavior.

A major reason for selecting an alcoholic population with which to work was the relatively successful results of the training program that Platt (Note 2) conducted with heroin addicts. His work suggested the possible relevance of such training programs for addict populations in general. It also seemed reasonable that alcoholics might benefit from a program that emphasized learning the habit of generating a variety of constructive coping behaviors in stressful real-life situations.

Study 1

Method

Subjects. The subjects were 63 male patients admitted to the alcoholism treatment unit (4-D) at the Veterans Administration Hospital in Buffalo, New York, during a 14-week period. The treatment program on this unit involves approximately 6 weeks of inpatient care. Only veterans are eligible for admission. The first 32 consecutive admissions were assigned to the control group. The assignment of 32 consecutive admissions to the treatment group, however, did not take place until 3-4 weeks later. This design was used so that treatment subjects would not begin their problem-solving skills training until all control subjects had been discharged from the program. If control subjects had been allowed to be in daily contact with treatment subjects for 6 weeks, their usefulness as a control group would have been diminished substantially. Although 32 subjects were assigned to the treatment group, one patient left the hospital shortly after attending the first treatment session and was dropped from the study sample. Thus, the treatment group was comprised of 31 subjects.

The subjects ranged in age from 23 to 66. Their average age was 45. With respect to educational background, 27% had completed eight grades or less, 59% had attended high school, 36% had completed high

school, 9% had gone to college, and 5% had received a 4-year college degree. Subjects' scaled scores on the WAIS Vocabulary subtest ranged from 5 to 16. The average scaled score was 10. Of the 63 subjects in the sample, 20% were single and had never been married, 30% were single but had been married previously, and 50% were currently married. In the 3 years preceding their admission to the hospital, 51% had held one steady job, 21% had held and lost several jobs, and 10% had not worked at all.

The control and treatment groups were compared with respect to age, educational background, scores on the Vocabulary subtest of the WAIS (which correlates .87 with the Full Scale WAIS score), marital status, and employment history. Results revealed that these two groups did not differ significantly on any of these variables.

Instruments and procedure. Two weeks after their admission, all subjects were administered the MEPS (Platt & Spivack, 1975).

This procedure makes use of story stems portraying situations in which a need is aroused in the protagonist at the beginning of the story and is resolved by him at the end. The respondent is required to complete the story by filling in those events which might have occurred between the arousal and satisfaction of the hero's need. (Platt & Spivack, 1975, p. 16)

The responses were scored for the number of discrete steps enumerated that effectively enabled story protagonists to reach the resolution points of the stories. The first administration of the procedure involved the random selection of 5 stories from the 10-story MEPS protocol. At the 6-week postadmission point, all subjects were administered whichever 5 stories they had not previously been given. Thus, subjects were administered the MEPS procedure both shortly after recovering from alcoholic detoxification and immediately prior to their discharge. Between the two administrations of the MEPS, treatment subjects completed 10 group training sessions in problem-solving thinking skills. They participated in these sessions in addition to all standard components of the 6-week treatment program. Control subjects participated in all aspects of the treatment program with the exception, of course, of the problem-solving training sessions. The nature of the training sessions will be explained in considerably more detail in Study 2.

On the basis of information gathered at the time of admission, each subject was also assigned a Ziegler-Phillips social competency score. Following the procedure outlined by Ziegler and Phillips (1962), the social competence measure is an additive score based on a subject's age, IQ, educational background, employment history, marital history, and occupational level. Subjects received a score of 0, 1, or 2 in each of these six areas. These six scores were totaled for each subject as an index of his social competence.

Finally, each subject received a score based on his responses to a series of standardized probes in a structured discharge interview administered to each patient by his group therapist shortly before discharge. The interview was structured to assess the comprehensive-

ness of subjects' discharge planning with respect to three key life areas: (a) employment, (b) living situation, and (c) free time. Four basic questions were used to explore the discharge planning that each patient had done in each area. These questions assessed (a) the specific plans a subject had made for dealing with this area of his life, (b) any obstacles that the subject anticipated might interfere with the plans he had made, (c) any alternative plans that the subject had considered before deciding on his chosen plan of action, and (d) any evidence that the subject could present of having already taken action to develop or implement his discharge plans. So that subjects' responses to the discharge interview could be scored, all discharge interviews were tape recorded.

Scoring. Scoring procedures for the MEPS testing were developed by Platt and Spivack (1975), whereas procedures for scoring the discharge interview were developed by me and involved only slight modifications of the MEPS scoring system. The scoring for both the MEPS instrument and the discharge interview was carried out by two senior psychology students who were unaware of the group membership of any individual protocol.

The scoring procedure for the MEPS testing involved noting (a) the relevancy, the number and kinds of means generated by a subject, (b) the number of elaborations or added details that a subject provided to explain each means, (c) the number of obstacles mentioned that might get in the way of the hero reaching the goal in the story, and (d) any mention of time elapsing before the hero reaches the resolution point of the story. A relevant means was defined as an instrumental act that enabled the hero to move toward or reach the goal in the story.

The scoring for the discharge interviews involved noting (a) the number of discrete, relevant means (instrumental acts) that a subject described as his plan for dealing with problems at work, home, or occupying his free time; (b) the number of obstacles mentioned that the subject felt might get in the way of his carrying out his plans, (c) the number of alternative plans that a subject had considered but decided not to put into action, and (d) the number of discrete acts in which a subject had engaged to formulate or implement his discharge plans.

The two raters were trained in the MEPS scoring procedures over a period of 1 month. As a first step, they familiarized themselves with the description of the scoring procedures provided by Platt and Spivack (1975). The final step, following several weeks of practice with the system, was the assignment of 15 hypothetical stories to each of the raters. The reliability coefficient computed between the total number of means assigned by the two raters to each story was .88 (Spearman-Brown prediction formula). Since the scoring procedures for the discharge interview were fundamentally the same as those for the MEPS scoring, no separate reliability coefficient was calculated for the interview scoring. The clear-cut scoring procedures for the Ziegler-Phillips competency measure have already been described in the preceding section and are outlined in greater detail by Ziegler and Phillips (1962).

Results

This study was conducted to explore the content and concurrent validity of the MEPS measure by examining the set of interrelationships between it and measures of subjects' IQ, social competence, and discharge planning. For the purpose of examining these relationships, the following specific scores were used: (a) The total number of relevant means served as a subject's MEPS score; (b) the subject's scaled WAIS Vocabulary score served as an index of IQ; (c) the subject's total score from the six life areas designated by Ziegler and Phillips (1962) served as the social competence measure; and (d) the subject's total points from the areas of work, living situation, and free time planning served as the discharge interview score (1 point for each discrete plan, obstacle, alternative, and action step mentioned).

When the interrelationships between scores on the first administration of the MEPS, the scaled Vocabulary score from the WAIS, and the Ziegler-Phillips social competency measure were explored, it was demonstrated that scores on the MEPS instrument were significantly related both to the social competency score ($r = .20$, $n = 58$, $p < .05$) and to the scaled Vocabulary subtest score ($r = .38$, $n = 62$, $p < .001$). However, when the effect of the Vocabulary score was partialled out of the relationship between the MEPS score and social competency score, the strength of the relationship decreased greatly and was no longer significant ($r = .06$). This result is unlike that reported by Platt and Spivack (1972a). They found that when general intelligence factors were removed from the social competency score, the relationship between the MEPS measure of interpersonal problem-solving cognition and the social competency score increased.

A second set of interrelationships that was explored examined the relationship between the scores on the final administration of the MEPS and both the discharge interview score and the scaled Vocabulary subtest score from the WAIS. Results revealed that the final MEPS score was related quite significantly both to the discharge interview score ($r = .38$, $n = 56$, $p < .002$) and to the original vocabulary measure ($r = .26$, $n = 55$, $p < .02$). When

the effect of the vocabulary score was partialled out of the relationship between the final MEPS score and the discharge interview score, the relationship between the two remained strong and significant ($r = .33$).

When the relationship between the WAIS vocabulary measure and the MEPS scores on both the initial and final MEPS testing was examined for the entire sample, there was a significant correlation between WAIS and MEPS scores at both points ($r = .38$ for initial, $r = .26$ for final). However, when relationships were examined separately for the control and treatment groups, it appeared that the problem-solving training sessions, to which only the treatment subjects were exposed, may have had some impact on the way in which the MEPS and vocabulary measures relate. For the control group, the correlation between the two measures changed from .43 (initial MEPS and vocabulary) to .32 (final MEPS and vocabulary). Both of these correlations were significant ($p < .007$ and $p < .04$, respectively). For the treatment group, on the other hand, the correlation coefficient changed from .36 (initial MEPS and vocabulary) to $-.05$ (final MEPS and vocabulary). Although the relationship between the two measures was significant for the treatment group at the initial MEPS testing ($p < .02$), the two measures were relatively unrelated at the time of the final MEPS administration ($p < .30$). Further, not only did the strength of the relationship decrease for the treatment group, but the valence shifted from positive to negative.

Study 2

Method

Subjects. The subjects are the same as described in Study 1.

Instruments and procedure. The treatment group of 31 subjects participated in a series of 10 60-minute sessions of interpersonal problem-solving group therapy. These sessions comprised a systematic intervention intended to increase participants' problem-solving skills. The 10 sessions combined and integrated a variety of materials prepared by Platt, Spivack, and Swift (1975) in a structured program of interpersonal problem-solving group therapy for adults. The 10 sessions were organized to teach a four-step approach to interpersonal problem solving. These steps were to (a) recognize that a problem exists; (b) define the problem; (c) generate a number of alternative solutions; and (d) select the best alternative after having looked ahead to imagine

the likely consequences of each. The treatment group of 31 subjects was divided into four subgroups (7, 6, 8, 10), each of which began the 10-session program approximately 1 week apart. The 10 sessions took place over a period of 4 weeks (2-3 sessions per week). All participants had spent at least 2 weeks in the treatment program before problem-solving sessions began.

As explained in Study 1, all subjects were administered the MEPS procedure 2 weeks following their admission to the hospital and again 4 weeks later. This arrangement provided a means of assessing the impact of the problem-solving sessions on the participants' problem-solving thinking skills. The timing was set so that all members of the treatment group had completed the 10-session program prior to the final MEPS administration.

In addition to the problem-solving sessions, one other independent variable was manipulated in this study. This variable was the preparation set of subjects who were about to be administered the structured interview to assess the quality and comprehensiveness of their discharge planning. One half of the subjects in both the control and treatment groups were randomly assigned to the condition in which they were told that their group therapist would interview them about the planning they had done for their discharge. They were so informed about an hour before they were to be interviewed. The other half of the subjects in each group was assigned to the condition in which they were not informed of the topic of the interview until it actually began. All of the subjects who were informed about the topic of their approaching interview were told by me that the interview would focus on their discharge

planning and would give them a chance to demonstrate to their group leader that they had given a lot of thought to the problems that they would soon be facing.

This manipulation was designed to serve two purposes. First, it provided a means of testing the efficiency of the problem-solving skills training as a means of increasing the effectiveness and thoroughness of subjects' planning for the real-life problems posed by their discharge. If the mere suggestion to control subjects that they ought to give a little thought to the problems that they would face following discharge should result in their performing as well as treatment subjects who have completed the problem-solving sessions, one would have to conclude that the sessions were a rather inefficient means of encouraging subjects to anticipate problems and plan ahead. Second, this manipulation provided a means of testing the degree to which the generalization of problem-solving skills taught in the training sessions was dependent on specific reminder cues.

Thus, the second part of the study provided two measures to assess the impact of the problem-solving training sessions. The first was the paper-and-pencil MEPS measure used to assess changes in cognitive problem-solving behavior. The second was the structured discharge interview to assess the quality of subjects' plans for dealing with impending real-life problems.

Results

MEPS measure. It was hypothesized that the treatment group would show significantly

Table 1
Pre-Post Comparisons of Story Elements

Statistic	Pretest			Posttest			Pre-post change		
	Control (32)	Treatment (31)	+ score	Control (27)	Treatment (29)	+ score	Control (27)	Treatment (29)	+ score
No. means							.29	3.50	
<i>M</i>	5.96	5.77		5.85	9.27		3.51	3.83	-3.32**
<i>SD</i>	3.33	2.61	.26	3.62	3.29	-3.70***
